It should be stated that this reactance program is only a small fraction of the engineering programs now available for the Pittsfield *705*. These programs comprise well over 100,000 instructions. The magnitude of the total job may thus be evaluated in terms of man-years and dollars expended. As an example of the results obtained, a final design of a large power transformer, requiring weeks by hand, is now done completely in a few minutes on the *705*. In many cases the contribution obtainable from the computer as a result of design optimization[8] is probably considerably more important than the manpower savings discussed in the foregoing.

Consider now some of the intangibles.

TIME

As already mentioned above, design calculations are usually processed in less than four hours in the *705*, while they would require weeks by hand. This collapsing of time is very valuable in design work, because it is possible to give better service to customers' inquiries and faster deliveries of their orders. In development work, it is possible to evaluate much faster the results of tests, and to decide immediately whether more tests are required. It is also possible to determine much faster the effect of new technological developments or new ideas on the product. Thus the computer makes available much sooner to the customer the results of research and development in the form of an improved product.

ACCURACY AND QUALITY

As has been seen, the reactance computations done on the computer are much more accurate than those done by previous methods. This is also true for many other design applications. This type of contribution, though difficult to measure in dollars and cents, is a very important addition to the net contribution. One possible way of measuring this advantage is to consider the savings effected by the avoidance of rejections in tests, and the savings obtainable by reduction of the design safety factors. If it is decided not to change the safety factors, the contribution is in effect passed on to the customer, in the form of a better product, more liberally designed. Even after evaluation in dollars of these two contributions, there remain the intangibles, such as increased customer good will as a result of higher quality and better service. These advantages, with their long-range profits, will in turn influence favorably the company's position in the mind of the public.

EFFORT

Even if no savings could be attributed to the computer, it would still save time and effort. With the present shortage of technical personnel, now vitally needed for national defense, it is important to utilize the available manpower as efficiently as possible. In effect, the computer frees engineers, mathematicians, and technicians from the effort of routine calculations and makes their time available for truly creative work. The long-range effect on the national economy of this particular contribution of the computer cannot be underestimated. Specifically, in the field of electric power, the load is expected to double every 10 years. This increase would require a corresponding increase in technical manpower of the utilities, manufacturers, research institutions, etc. Since the number of electrical engineers expected to graduate in the next 10 years will certainly not double, the computer will be one of the most effective means for decreasing the gap between requirements and availability.

Effect on Personnel

It is certain that computers will not cause any significant displacement of technical personnel in the foreseeable future. Even for the most typical data-processing applications, for instance, in insurance companies, the impact of office automation on personnel is much less pronounced than was feared or expected. Yet some of these applications are often made for the specific purpose of reducing clerical costs. On the contrary, it may be stated that computers are used in engineering not so much to reduce the number of engineers and technicians, but rather to alleviate their shortage, improve quality and service, reduce time, and take care of the increase in business.

Perhaps more interesting is the effect on the type of personnel which will be required in a future organization that makes extensive use of computing facilities. Anticipating this is somewhat like gazing into a crystal ball, but still worth considering.

It may be assumed that, for conventional methods, the distribution of the required skills follows a Gaussian distribution curve. The effect of the computer on the personnel required would appear to reduce the frequency of persons with average skill and, on the other hand, increase the frequency of persons with higher and lower skills. In fact, the skill required by the procedure and programming specialists is higher than average, and the emphasis will be on increasing the development effort to improve the quality of the product. Since the computer can produce results faster and in much greater quantity than previously, higher ability will be required to keep up with its pace and make optimum use of the new information available. This, of course, is a restatement of the familiar fact that a machine is no better than the persons who are using it. Since computers represent high initial investments and yearly expenses, it is necessary to employ high-quality personnel in order to obtain adequate returns. On the other hand, the processing of data by means of the computer can be done by young engineers and technicians, with less skill than that of the average engineer. This trend should be valuable in attracting more engineers toward more interesting, challenging, and higher-paid work, and in utilizing technicians to release engineers for jobs which require the complete application of their skills. The training of young engineers is facilitated and accelerated by the use of the computer. Consider, for instance, the training of a designer: once he has mastered the fundamentals, he can make many more designs on the computer than by hand in the same period and he can observe more readily the effect of changing the specifications or the design variables, and compare alternate forms of constructions.

Since engineers are normally progressive individuals, eager to use the best available tools, the effect on the morale of the engineering force of installing a computer will be good, provided it is explained thoroughly to all engineers before its installation. It must be made clear that it is a willing and docile helper, an extension of their skills, rather than a mysterious black box with push-buttons which threatens to take away their jobs. Programming courses, either mandatory or with voluntary participation, are also very effective in removing the aura of mystery and misunderstanding which often accompanies the word "automation," and in spurring all engineers to make optimum use of the new facility.

Summary and Conclusions

The foregoing is an endeavor to analyze the most important problems facing all persons planning or managing a computer installation for engineering work. The selection of the applications to be programmed, the selection of the computer, and the problems of conversion from one computer to another are discussed. The various steps for programming and running an important engineering problem, and the organizational patterns which arise from these activities are described. The economics of computer installations are discussed at length and it is shown that the conventional accounting methods are inadequate for evaluating the over-all contribution of the computer. Finally, the effect on the number, quality, and morale of personnel is considered. This analysis is supplemented by actual examples taken from the authors' experience.

The discussion leads to the following conclusions:

1. Applications should be selected which have a high degree of repetitiousness. They should be planned and evaluated as a group, rather than individually.

2. The selection of the type and size of computer depends upon the applications considered, the amount of usage, and organizational considerations. Larger and more expensive computers are required as the volume and the amount of engineering data processing increases.

3. Conversion from one computer to a larger and more economical computer may sometimes be made simpler, faster, and cheaper by devising automatic programming techniques to simulate the work of the smaller computer on the larger.

4. Various patterns of organization are possible, depending upon the circumstances. In any case, three kinds of work may be identified: engineering work, programming work, and computer operations. A closed shop appears more advantageous for large-scale machines and for highly repetitive applications with large data-processing content, such as the design of electric apparatus.

5. Since the engineering work done on a computer is seldom directly comparable to the work previously done by hand, it is difficult to determine savings by ordinary accounting methods. A method is presented for determining the computer costs, the gross contribution, and the net contribution attributable to the computer.

6. In most cases the contribution of the computer in the areas of optimization, reduced time, increased accuracy and quality, and the freeing of technical manpower

for creative effort, is more important than the savings obtainable through reduction of technical personnel.

7. The effect of computers on the number of engineering personnel will be relatively small. More important is the effect on the quality of technical personnel which will be required in the future, on their training, and on their morale.

8. The over-all contributions to date of digital computers to the advancement of science and engineering are significant, technically and economically. It is felt, however, that engineers are just starting to learn how to apply this powerful innovation and that future contributions will be even more important.

9. A thorough understanding of the theory and practice of applying digital computers to engineering problems will be necessary to achieve optimum utilization of this revolutionary new tool.

Discussion

H. R. J. Grosch (International Business Machines Corporation, New York, N. Y.): A useful rule for forecasting computer savings is that "economy is as the square root of the speed."[1] That is, to reduce the cost of a calculation by a factor of 10, one must utilize speeds faster by a factor of 100.

The authors mention, as certain advantages of the "closed shop," professionally expert programming, more efficient operation of the computer, and opportunities for development of advancement of personnel. The list may be extended to include:

1. Interest in improved equipment, and in more advanced methods of programming currently installed equipment.

2. Attendance at specialized meetings, membership in specialized societies, and subscriptions to specialized publications.

3. Contributions to the profession.

4. A center which can advocate computer applications in other areas such as accounting, production control, sales analyses, operations simulation.

Establishing the contribution of the computer operation to the business, in order to obtain or increase financial support, is described as a major task. One method which I adopted in several large installations alleviates the difficulty: services are sold to various technical projects and functions, on an hourly basis. Rates for machine time and for programming personnel are established so as to liquidate expenses at the predicted utilization rate for the budget period. As the authors indicate, utilization often builds up with unexpected rapidity; rates may be lowered or rebates given, or the surplus used for advanced personnel training, for support of programming research, or to experiment with new areas of application not yet able to pay their way.

The burden of proving the advisability of using the computer group is spread among project and functional managers. Budget problems are minimized, being reduced largely to collecting the estimates of prospective users and multiplying the sum by an experience factor to allow for the new work always to be expected. Multiple-shift operation permits a very flexible capacity, and this flexibility may be increased by utilizing service bureaus and programming subcontractors; thus, proceeding for a year or two while experience accumulates need not be very difficult.

C. G. Veinott (Reliance Electric and Engineering Company, Cleveland, Ohio): I agree qualitatively with a large part of this interesting paper and with most of the authors' conclusions. However, I believe that the economics as they see them are not necessarily applicable to the needs of a smaller engineering organization; it is with such cases that the following remarks are principally concerned.

In general, we agree with the authors and with Harder that the cost per computation is less on a large-sized expensive computer than on a small one. This, of course, assumes that there is sufficient work load to keep the large-scale computer more or less continuously busy. It seems to me that the most economical computer is the smallest one that will just handle the work load adequately. Of course, the work load normally increases rapidly and some anticipation of future needs must be made. The authors refer to the IBM *650* as a medium-sized computer which they report as having an annual budget of about $100,000 or upward. Excluding the operating personnel, the machine rental of an IBM *650* together with associated equipment is approximately $5,000 per month. The monthly rental on an Alwac III with a 4,000-word drum, including maintenance, is approximately $2,000 per month, or less than half the rental cost of a *650*. With an 8,000-word drum, the Alwac rental is only about $2,200 per month. The computing speeds are roughly comparable, or are at least of the same magnitude. Carr and Perlis have compared the speeds of these two computers,[1] giving the speed of the Alwac III as compared with that of the *650* as 59% in "normal" mode and 115% in "optimum programming." But the relative storage capacities of these two computers are significant and pertinent in handling the authors' problem and mine. The *650* has a storage capacity of 2,000 words, which can be either instructions or data. Our Alwac III, with 4,000-word drum, can store 8,000 instructions or 4,000 items of data. We actually have in operation on the Alwac III one program consisting of 5,200 instructions, 390 items of data, and 520 program constants. With an 8,000-word drum, programs of over 10,000 instructions are practicable.

There are perhaps two basic reasons for going to a larger than medium machine, say a *705* versus a *650:* faster speed and larger storage capacity.

With our Alwac III there is so much storage capacity that we are not forced to use a larger machine at somewhat more than ten times the cost. Since we can handle all the calculations needed in the foreseeable future on a 1-shift basis, it would not be economical for us to multiply our costs by 10 in order to increase the speed by a factor of 10, or even 50 or a 100.

We point out for the benefit of others with similar problems, who have been prevented from using automatic electronic computing because of the tremendous cost of the large-scale high-speed machines such as an IBM *704* or *705*. Similar storage capacity for needed long programs may be obtained at a small fraction of the cost of these machines.

The argument is often advanced that the low storage capacity of the *650* is entirely adequate, because the program may be worked in parts. The authors have brought out clearly that often this is not the case. To accomplish synthesis design, very long loops are needed. Given a machine that will store, say, 1,500 instructions and 500 words of data, the maximum length of loop is 1,500 instructions, and this frequently is not enough.

The authors mention a program for transformer reactance calculations that contains 2,000 instructions. I should be interested in knowing what lengths of programs the authors are using.

We particularly agree with the authors conclusion that applications should be selected which have a high degree of repetitiousness. The selection of type and size of computer depends upon the applications considered but, as we have pointed out, it is not necessary to go to a million-dollar machine to obtain high storage capacity. In our experience, we too have found that the closed shop appears more advantageous. The over-all contribution and the effect on personnel have been substantially the same as reported by the authors, but the cost of installation is so much less that the economic justification for it is more readily apparent and we have not had to go to such great lengths to justify the economic basis of the installation.

1. Applied Digital No. 4: Small-Scale Scientific Calculators, **J. W. Carr, III, A. J. Perlis.** *Control Engineering*, New York, N. Y., vol. 3, no. 3, Mar. 1956, pp. 99–104.

Ned Chapin (Stanford Research Institute, Stanford, Calif.): The authors say that there are some computer applications which cannot be done well on small computers; that to handle some applications adequately requires large-scale computational and data-processing capacity. This is also true of some business data processing applications, especially those which attempt to improve the quality of information flowing to management.

The authors suggest a threefold organizational structure for effective computer utilization, and a closed-shop organization of programming effort. These suggestions apply well to many data-processing installations, especially those in which scheduling of data-processing accomplishment is critical.

In the section "Economics" the facts are summarized concerning the introduction of an automatic computer being typically accompanied by a complex set of changes in company procedure. The point is made that because these changes occur as a "package," it is difficult to associate any specific dollar figure to the specific contribution of just the automatic computer.

In making feasibility studies and in justifying the continued use of automatic computers in data-processing installations in business, it has been my observation that management frequently want something that they can point to as indicating that they are "doing the right thing." Often, in order to be secure in the knowledge that the computer installation will do well, management wants to have a "saving" figure to point to, and say, "This is evidence that things are (or will be) in good shape."

Because of the complex set of changes noted previously, the paper suggests talking with management in terms of a "net contribution," not a savings. Can the authors tell us, based on their experiences, the response of their management to this concept? If intangibles are the basis for using the automatic computer, it would relegate a net contribution figure to a position of mere "window dressing." If management has objections to the use of the concept of a net contribution, how would the authors meet this objection?

As to the costs of operating an automatic computer, the literature on costs of programming is referred to, but the authors do not indicate what their cost experience has been. Could we have a summary of what they would include in the cost of programming, and of their experience, on a cost-per-instruction, written-and-debugged basis, for various types of programs?

The discussion of the intangible benefits obtainable through the use of an automatic computer applies equally well to most data-processing installations, and I would agree that these intangible benefits are sufficiently substantial so that they should be kept clearly in mind and emphasized.

P. A. Abetti and S. B. Williams: We wish to thank the discussers for their interesting and thought-provoking discussions. Time and space do not permit us to answer them in detail, so we will limit this closure to the most important points. We are gratified that the data given in the paper verify a posteriori the rule first derived by Dr. Grosch in 1953, a time which belongs to the early history of digital computers. In fact, square roots of the relative speeds given in Table II of the paper are 0.15 for the CPC and 0.016 for the *705*. These values are in good agreement with the relative costs per calculation given also in Table II, namely 0.11 for the CPC and 0.013 for the *705*.

Dr. Grosch discusses also the service bureau approach for various computer applications, which has been used successfully in many installations. In general we agree with his conclusions, but it should be noted that the sharing of the charges may turn out to be unfair, if major programming methods, important subroutines, and utility programs are to be developed first. In this case, the first application on the machine will take the expense and the brunt of this major effort, and successive applications by other groups will require comparatively much less time, effort, and expense. This is why we feel that the economics of applications using common portions of programs should be considered as a whole, since this will justify some applications which would not be justified if considered by themselves. Furthermore, the separate approach to the computer by the various groups may result in an obstacle to integration, and this, as is well known, may be a serious drawback, technically and economically.

Mr. Veinott's discussion is very interesting because it presents experience with a smaller and considerably less expensive computer than the *705* in the field of design of electric machinery. It is clear that there is no need to go to a larger computer, if the one used has sufficient speed and capacity for the applications considered. On the other hand, as is also confirmed by Dr. Grosch, in many cases the load builds up much faster than expected, and many problems, such as reprogramming for conversion, may be avoided by obtaining from the beginning some extra speed and capacity. As mentioned in the paper, a great variety of engineering programs are now being run on the Pittsfield *705*. Some of them, written according to the Print I programming system, may have a few hundred instructions. Typical examples are the determination of the real and complex roots of polynomials, the inversion of matrices, the evaluation of complicated mathematical expressions, curve fitting by the least square method, etc. Others, written in symbolic language or autocoder, may have up to several tens of thousands of instructions.

Mr. Chapin's discussion is also of great interest, since it emphasizes the similarity between engineering and data-processing applications of digital computers, and shows that many problems and solutions are common to both cases. A typical and most important example is the problem of evaluating or measuring the contribution of the computer, for the benefit of management. In our case, the proposed installation of the *705* in the power transformer department was carefully reviewed by management and by the appropriate financial components, according to the established procedures of the General Electric Company. Similarly, the progress obtained since February 1958, when the *705* started operating, is being reviewed constantly according to these procedures. In the process of furnishing the required data, and in many discussions with their associates, the authors felt that it would be advantageous to supplement (but not to replace) this method of evaluation by another method, which would overcome some of the difficulties mentioned in the paper, and of which Mr. Chapin is well aware. For these reasons they proposed the concept of "net contribution," which has been favorably received. It should be emphasized again that, as mentioned in the paper, this is no substitute for the "savings" which every company will want to determine according to its established procedures.

As discussed in the paper, the costs of programming vary over an extended range depending upon the type of application, the computer, the programming system employed, the ability of the programmer, the input and output requirements, the integration between various programs, etc. For this reason we only indicated the range, feeling that specific figures would not be very significant. In the cost of programming we included: 1. the procedural work required to define the problem, the input and output requirements and the general method of approach; 2. numerical analysis work, which may be required for certain engineering problems; 3. preparing rough and detailed flow charts; 4. coding; 5. key-punching and verifying the program and supporting data; 6. conversion to tape of program and supporting data; 7. assembly; 8. debugging; and 9. final verifications of results by trial runs. There is a question whether the cost per instruction is an adequate measure of the cost of programming. Consider, for instance, two equivalent programs, a "tight" one with relatively few instructions, many loops, and no repetition; and another with many instructions, few loops, and several repetitions. Both programs perform the same function and probably will cost about the same, if prepared by programmers of the same ability. The first, however, will have a higher cost per instruction than the second. In a tight program the total cost may be proportional to the square rather than to the first power of the number of instructions, and therefore the cost per instruction will depend upon the length of the program.

For all these reasons, we can answer Mr. Chapin's question only by stating that our experience has yielded an extended range of dollars per instruction. At one extreme are relatively simple mathematical programs written in the Print I system, which cost less than $1.00 per instruction. On the other extreme are complex engineering data-processing programs, which require considerable procedural work, detailed and complex input and output formats, and a considerable amount of supporting data. Some of these were revised, partially or completely, one or more times and their cost amounted to several dollars per instruction, which verifies the values from $4.00 to $10 quoted in the literature. Of course, all intermediate conditions and corresponding values are possible.

In conclusion, we should like to stress that the art of applying digital computers to engineering and data-processing problems is still in its infancy, and that progress can only be furthered by a free and frequent exchange of ideas, data, and experience among the many users of this powerful new tool. For this reason, we are grateful to the discussers for their contribution and hope that out paper will be followed by many others in the broad area it attempted to cover.

Surge Measurement Errors Introduced by Coaxial Cables

J. H. PARK
MEMBER AIEE

NEARLY all surge or impulse voltage measurements involve the use of a cathode-ray oscillograph (CRO) and measuring cable. If an ideal cable is assumed, i.e., one with no losses and a surge impedance which does not vary with frequency, conditions giving zero measurement error can readily be set up. However, all cables have some attenuation and their surge impedance is never the same for all frequencies.[1,2,3] In low-voltage impulse work (where very short cables can be used) such factors may be negligible under certain conditions, but for measuring high-voltage surges a fairly long cable (50 feet or longer) is usually required and possible errors caused by the cable should be considered, especially for measuring steeply rising surges. The purpose of this paper is to discuss such errors and devise methods for measuring and minimizing them.

Attenuation Errors

Cable losses are caused by the resistance of the center conductor and outside sheath together with conductance and dielectric hysteresis in the insulating material between conductors. Losses are usually expressed as an attenuation in decibels per 100 feet at a fixed frequency and in general the logarithm of attenuation in decibels increases in direct proportion to the logarithm of the frequency. For any given surge it is theoretically possible to determine the change in peak value and waveform caused by cable attenuation by using the known values of attenuation at various frequencies and the Fourier integral procedure. However such a procedure is time consuming and would have to be done for each different waveshape of applied surge. Also, it is not completely reliable unless the variation of phase shift with frequency is also taken into account.

An experimental approach is much easier to apply and probably more reliable. One method is to arrange the surge generating circuit so that the pulse to be measured, or one similar to it in shape and rate of rise, can be accurately repeated from shot to shot. (The peak value can be repeated by using a linearly rising voltage chopped with a sphere gap.) Oscillograph records are then taken with (1) a measuring cable of minimum length L, (2) a cable twice this length $2L$, and (3) a cable three times this length $3L$. If the oscillograms obtained under these three conditions are appreciably different in waveshape or peak value, a cable having lower attenuation should be used or a correction for attenuation computed. Polyethylene coaxial cables are used to obtain low attenuation and attenuation can be reduced by using a cable of minimum length and one whose center conductor is large.

For surges which, in general, rise linearly and are chopped by the sparkover of a gap, a correction for the error in peak-voltage measurement due to cable attenuation can be determined. This is done by obtaining values of peak voltage with the three different cable lengths, L, $2L$, and $3L$ as indicated. The decrease in peak voltage ΔV when the cable length is changed from L to $2L$ should be the same as that obtained when the cable length is changed from $2L$ to $3L$, within the accuracy of the measurements. The average of the two values of ΔV is added to the peak voltage obtained with a cable of length L to correct for attenuation.

This method of correcting for cable attenuation was used during an investigation of the change in sparkover value of standard 12.5-cm (centimeter)-diameter spheres set 6 cm apart as the rate of rise of the applied voltage was increased. Values of ΔV were obtained for rates of voltage rise from 10 to 10,000 kv per μsec (microsecond). They were computed as a percentage of total voltage and plotted against rise time (time to sparkover) as obtained by dividing peak voltage by rate of rise. Results are shown in Fig. 1 for *RG-58/U* and *RG-8/U* coaxial cables.

Errors Due to Cable Termination

For most impulse and surge work the CRO cable is terminated by a noninductive resistor which is considered to be equal to its surge impedance in ohms and thus to produce no errors due to reflections. This assumption is not strictly justified, because the surge impedance of all cables varies with frequency and reflections due to different types of surges cannot all be prevented by a terminating resistor of fixed value. The change in impedance with frequency is introduced by (1) the cable resistance and conductance which put a $j\omega$ term in the impedance and can only be neglected over certain frequency ranges and (2) the change in cable inductance caused by nonuniform distribution of current in the sheath and center conductor as frequency is increased. This last factor is actually due to skin effect which also causes a change in resistance with frequency and further complicates factor 1.

Thurston[3] gives a plot in arbitrary units showing the variation of characteristic impedance with frequency for nominal 50-ohm polyethylene cables. Below 100 kc the impedance is given as constant and equal to 55 ohms. From 100 kc to 10 megacycles there is a gradual change from 55 to 50 ohms and it remains at 50 ohms for higher frequencies. Thus if a 50-ohm terminating resistor is used with such a cable (as would normally be

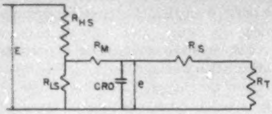

Fig. 2. Circuit used for computing divider ratio with direct voltage applied

the case since such cables are intended for high frequencies and their surge impedance values are given for these high frequencies) there would be a missmatch of 5 ohms for frequencies below 100 kc. This could cause an error of 5% when measuring slowly rising surges, square waves, or 1.5×40-μsec full-wave surges. If a higher value of resistance is used for the termination, say 55 ohms, which would reduce the measurement error for slowly rising surges or full waves, then errors up to 5% would be introduced in measuring steeply rising chopped waves.

In order to measure the actual values of these errors, a better method of terminating the measuring cable at the CRO deflecting system is needed. If another length of the same type of cable is used as a termination, the only discontinuity at the oscillograph would be that caused by the capacitance of the deflecting plates, which is negligible except for very steeply rising surges. An extremely long cable cannot be used because of the effect of its resistance (to be considered shortly), but a sufficient length can probably be used so that reflections of steeply rising chopped surges do not get back to the oscillograph until peak voltage has been reached. Thus a terminating cable with a resistor at its end whose value is chosen to give no reflection for slowly rising surges should serve to eliminate termination errors for all types of surges. The effect of the resistance of a terminating cable will first be considered, then an experimental method for deciding when such a cable is needed and its length will be described.

Table I. Change in Divider Ratio with Time Introduced by Resistance of Terminating Cable for a Suddenly Applied Voltage

Computed by Applying Equation 3 to the Case of a Very-Long RG-58/U Terminating Cable with R_{HS}=1,000 Ohms and R_{LS}= 10 Ohms

Time After Application of Voltage, μsec	Divider Ratio $e_a(t)/e(o,t)$
0	119.5
0.2	119.2
0.4	118.9
0.6	118.6
0.8	118.2
1.0	118.0
1.5	117.4

The effect of the resistance of a terminating cable on CRO measurements depends upon the circuit to which the CRO measuring cable is connected. A typical measuring circuit is shown in Fig. 2 where resistance only is considered since a d-c applied voltage is assumed. The low side of a resistance divider ($R_{HS}+R_{LS}$) is shown connected to the deflection plates of a CRO by a measuring cable of resistance, R_M. The measuring cable is terminated by a longer cable of resistance, R_S, which in turn is terminated by R_T.

For a d-c applied voltage with $R_M=0$:

$$e=E\frac{R_{LS}}{R_{LS}+R_{HS}\left(1+\dfrac{R_{LS}}{R_T+R_S}\right)} \tag{1}$$

The error introduced by neglecting R_S is small if $R_S<<R_T$ and it is considerably reduced if $R_{LS}<<R_T$. This d-c computation gives the maximum error likely to occur due to resistance of the terminating cable during surge measurements. An actual computation is possible for a surge voltage applied at E (Fig. 2) if the general solution of transmission-line equations (which take cable resistance into account) is used. Weber[4] has indicated, in general, how to apply LaPlace transform methods to such problems and he has shown that for a suddenly applied voltage, the current taken by an infinitely long cable decreases with time, i.e., in effect the surge impedance increases with time. By using similar methods, a solution was derived and is given in Appendix I for the voltage $e(o,t)$ at the deflecting plates of a CRO which are connected by a negligibly short measuring cable to the low side of a resistance divider, when voltage is suddenly applied to the divider high side. The measuring cable is assumed to be terminated by an infinitely long length of cable of the same type and its resistance, inductance, and capacitance are considered. The result is derived as an infinite series and five terms, which give sufficient accuracy if $R_{LS}\leqq 10$ ohms, are given by equation 3. If cable resistance is negligible ($r=0$) the divider ratio does not change with time and equation 3 gives the same results as equation 1 with $R_S=0$ and $R_T=\sqrt{l/c}$.

It is difficult to deduce general relations between cable resistance and measurement accuracy from these theoretical results because of the assumptions made in their derivations and because the results are in the form of an infinite series. However, some conclusions can be drawn by applying equation 3 to a specific case. Computations were made for *RG-58/U* coaxial cable, $R_{HS}=1{,}000$ ohms, and $R_{LS}=10$ ohms. Results are shown in Table I. At zero time the divider ratio is the same as that obtained on direct current with the cable replaced by a resistor equal to its surge impedance. Divider ratio decreases as time increases and at infinite time reaches the value that would be obtained on direct current with an open circuit at the CRO. For a finite length of cable it can be assumed that the voltage at the CRO would be the same as for an infinite cable up to the time when the first reflection from the end of the cable gets back to the CRO. For a terminating resistor at the end of this cable equal to its impedance as obtained by neglecting resistance, this reflection would be such as to eliminate any further change in divider ratio. Thus for a 500-foot length of *RG-58/U* cable the maximum change in ratio for a suddenly applied voltage would be that given in Table I for time equal twice the pulse travel time or 1.5 μsec. This corresponds to an error of 1.8%, which agrees with the value obtained from d-c considerations using equation 1 and saying the error is the difference found in computing e for $R_S=0$ and $R_S=7$ ohms (the resistance of 500 feet of *RG-58/U*).

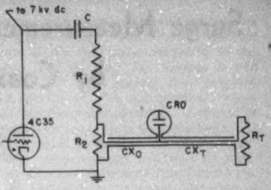

Fig. 3. Circuit used in measuring effect of terminating cable on divider ratio

In order to obtain an experimental verification of the error caused by cable resistance, the setup shown in Fig. 3 was used. Capacitor C was charged to about 7 kv and then discharged through noninductive resistors, R_1 and R_2, by the hydrogen thyraton. The voltage across R_2 was measured by connecting a 45-foot length of *RG-58/U* coaxial cable, CX_0, from R_2 to the CRO deflection plates. The termination for cable CX_0 consisted of either a 500-foot length of *RG-58/U* coaxial cable, CX_T with R_T at its end, or a 3-foot length of *RG-58/U* coaxial cable with R_T at its end. R_T was a noninductive resistance of 55 ohms which equals the surge impedance of the cable for slowly rising surges or full waves. In order to obtain a direct comparison of

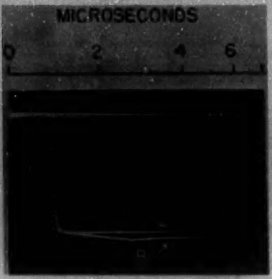

Fig. 4. Oscillograms showing effect of resistance of terminating cable (RG-58/U) obtained with setup shown in Fig. 3 with $R_1=150$ ohms and $R_2=50$ ohms

A—Obtained with $CX_T=3$ feet
B—Obtained with $CX_T=500$ feet

voltage for the two lengths of terminating cable, repeat shots were taken on the same oscillogram with everything the same except terminating cable length. An example is shown in Fig. 4, obtained with $R_1=150$ ohms and $R_2=50$ ohms, which gives a difference large enough to be readily noticed. The long terminating cable gives a higher voltage at the CRO as seen by comparing the two traces. The maximum difference is about 5% as determined from measurements on the oscillogram. By using equation 1 which was derived for a steady d-c applied voltage and the measured value of cable resistance (7 ohms), the change in measured voltage introduced by cable resistance can be computed and it agrees with the experimentally determined value to within 0.5%.

Experimental Check of Cable Termination Errors

Measurement errors introduced by the method used to terminate a CRO measuring cable depend upon the type of surge being measured and the values of resistance used for the divider. They cannot be assumed to be negligible. While theoretical computations are useful in estimating such errors the final check on their magnitude must be obtained experimentally.

For measuring 1.5×40-μsec full waves or those chopped on the tail, the cable surge impedance may be considered as the value obtained at low frequency (below 100 kc). Thus a fixed resistor located at the CRO can be used to terminate the cable. A circuit similar to that shown in Fig. 3 should be used to determine the exact value of R_T. R_1 and R_2 should be noninductive resistors and the value of R_2 should be approximately equal to the surge impedance of the measuring cable to prevent confusion caused by reflections from the input end of the cable. The terminating cable CX_T should be at least 100 feet long and several different values of R_T should be tried so that the one giving minimum reflections can be chosen. This was done for *RG-58/U* and *RG-8/U* cables; the results are shown by the oscillograms of Figs. 5 and 6. The reflections are easily identified as small pips on the flat top of the suddenly applied voltage. If the pip introduces a small step discontinuity which persists for several microseconds, it indicates that R_T is too large if the step increases the measured voltage, or too small if it decreases the voltage. When R_T is exactly right there will be no step discontinuity but usually a pip of short duration which is a reflection of the high-frequency components associated with the sudden change in voltage. From the measured magnitude of the step discontinuity a value for the correct terminating resistor (for full-wave measurements) was obtained from each CRO record. For each type of cable, measurements were obtained on ten or more oscillograms and the maximum variations from the average value were ±1 ohm. The average values were 55.7 ohms for *RG-58/U* cable and 52.7 ohms for *RG-8U* cable.

For measuring steeply rising surges, chopped on their rising front, a terminating resistor whose value had been determined as described would introduce an error due to reflection of the high-frequency components of surge. Thurston's[3] data on 50-ohm cables would indicate that this error might be as high as 5%; however, it would be expected to vary considerably with rate of voltage rise or time to chopping and probably to some extent with cable type and construction. This error was determined experimentally for *RG-58/U* and *RG-8/U* cable by obtaining CRO records of linear rising chopped surges of various durations using both a 3-foot and 200-foot terminating cable. The resistor, R_T, at the other end of the cable was made approximately equal to the full-wave surge impedance of the cable as given in the preceding paragraph. For each rate of voltage rise, peak voltage was duplicated on successive shots by using 12.5-cm spheres spaced 6 cm for chopping. For the longer duration surges the measured peak value was the same for both 3- and 200-foot terminating cables. As the duration of the surge was decreased, a point was reached where higher measured peak values were obtained with the 3-foot cable than with the 200-foot cable. This

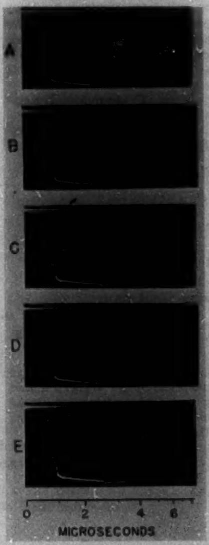

Fig. 5 (left). Oscillograms showing reflections from the end of a 500-foot-long RG-58/U cable, terminated with various values of R_T, as given in ohms below. Obtained using setup shown in Fig. 3 with $R_1=150$ ohms and $R_2=50$ ohms

began to occur for durations of about 0.2 μsec and for 0.1-μsec rise time the difference was 1%. For a time to chopping of 0.05 μsec, differences in measured voltage for the 3- and 200-foot terminating cables were determined for several different values of terminating resistor, R_T. From these results the correct value of R_T for a surge of 0.05-μsec rise time was found to be 53.8 ohms for *RG-58/U* cable and 50.9 ohms for *RG-8/U* cable. Thus the change in surge impedance is only about 2 ohms in going from full-wave to very-steep-wave (0.05-μsec duration) measurements, which is considerably less than the 5-ohm change deduced from Thurston's data. This 5-ohm change in impedance might be attained if shorter duration surges were used.

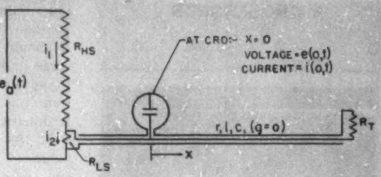
For measuring very short duration surges it would be advisable to use a terminating cable with a wave travel time down and back of 0.2 μsec, i.e., about 100 feet for *RG-8/U* or *RG-58/U* cable. There remains a possible error due to resistance of the terminating cable. Equation 1 can be used to compute an upper limit for this error when the low-side voltage of a resistance divider is being measured. For 100 feet of *RG-8/U* (resistance = 0.3 ohm) this error is less than 0.5% for all values of R_{LS} and R_{HS}. For 100 feet of *RG-58/U* (resistance = 1.4 ohms) this error is somewhat larger, but it would be less than 1% for $R_{LS} \leqq 10$ ohms. Thus a 100-foot terminating cable with R_T equal to its surge impedance for full waves would be suitable for measuring all types of surges. The 100-foot terminating cable is not needed for measuring surges with rise times greater than 0.2 μsec.

Conclusions

The possibility of errors caused by attenuation introduced by the measuring cable and the method used for terminating this cable should be considered in measuring high-voltage surges.

Attenuation errors are quite easily determined experimentally for linear-rising chopped surges and a procedure for doing this has been described. The results obtained indicate that *RG-8/U* coaxial cable has less attenuation than *RG-58/U*. If *RG-58/U* cable is used a correction for attenuation should be applied, even for full-wave measurements.

Fig. 7. Circuit used for computing divider ratio when a surge voltage, $e_a(t)$, is applied



Since the surge impedance of coaxial cables is not independent of frequency, a fixed terminating resistor at the CRO deflection plates is not satisfactory for all types of surges. By using a terminating cable of the same type as the measuring cable, a method was devised to obtain a termination satisfactory for all types of surges. This method was used to measure reflection errors introduced by a fixed terminating resistor at the CRO deflecting plates. It was found that such errors were less than 1% when using *RG-58/U* or *RG-8/U* cable to measure surges with rise times (times to chopping) greater than 0.2 μsec.

Appendix I. Derivation of Divider Ratio for a Suddenly Applied Voltage with Terminating Cable Constants r, l, and c Considered

Referring to the notation given in the circuit diagram of Fig. 7, the purpose of this derivation is to obtain an expression for $e(o, t)$ in terms of $e_a(t)$ and the circuit constants. The measuring cable, from R_{LS} to CRO, and the terminating cable, from CRO to R_T, are assumed to be taken from the same reel. The measuring cable is short enough so that its resistance can be neglected. The terminating cable is very long and terminated by R_T, which is equal to its surge impedance.

Referring to Fig. 7, the following equation can be written:

$$i_1 = i_2 + i(o, t)$$

$$e_a(t) = [i_2 + i(o, t)]R_{HS} + i_2 R_{LS}$$

$$i_2 R_{LS} = e(o, t)$$

From these equations

$$e_a(t) = e(o, t)\left[1 + \frac{R_{HS}}{R_{LS}}\right] + i(o, t)R_{HS}$$

Its Laplacian transform is

$$Le_a(t) = E(o, p)\left[1 + \frac{R_{HS}}{R_{LS}}\right] + I(o, p)R_{HS} \quad (2)$$

$E(o, p)$ and $I(o, p)$ are given by equations 17 and 18, respectively, of Weber's article on traveling waves on transmission lines.[4] For an infinite line with no initial voltage or current, these equations reduce to

$$E(o, p) = B$$

and

$$I(o, p) = \frac{B}{Z_c}$$

where B is a constant and

$$Z_c = \sqrt{\frac{r + lp}{g + cp}}$$

Substituting these in equation 2 and solving for B gives

$$B = Le_a(t)\frac{1}{1 + \frac{R_{HS}}{R_{LS}} + \frac{R_{HS}}{Z_c}}$$

Let

$$1 + \frac{R_{HS}}{R_{LS}} = N$$

then

$$E(o, p) = Le_a(t)\,\frac{Z_c}{NZ_c + R_{HS}}$$

For a suddenly applied voltage

$$Le_a(t) = \frac{1}{p}$$

and for

$$g = o,\ Z_c = \sqrt{\frac{lp + r}{cp}}$$

$$\mathrm{E}(o, p) = \frac{1}{p}\,\frac{\sqrt{lp + r}}{N\sqrt{lp + r} + R_{HS}\sqrt{cp}}$$

To find the inverse transform of $E(o, p)$ which is the voltage at the CRO, use the binomial theorem to expand the fraction in the foregoing equation giving

$$E(o, p) = \frac{1}{pN} - \frac{R_{HS}}{pN^2}\left[\frac{cp}{lp + r}\right]^{1/2} + \frac{R_{HS}^2}{pN^3}\left[\frac{cp}{lp + r}\right] - \frac{R_{HS}^3}{pN^4}\left[\frac{cp}{lp + r}\right]^{3/2} + \ldots$$

Take the inverse transform of each term on the right side of this equation to obtain $e(o, t)$. Going as far as available tables of transforms allow gives

$$e(o, t) = \frac{1}{N} - \frac{R_{HS}}{N^2}\left[\frac{c}{l}\right]^{1/2} \epsilon^{\frac{-rt}{2l}} I_0\left[\frac{rt}{2l}\right] + \frac{R_{HS}^2}{N^3}\,\frac{c}{l}\,\epsilon^{\frac{-rt}{l}} - \frac{R_{HS}^3}{N^4}\left[\frac{c}{l}\right]^{3/2} \epsilon^{\frac{-rt}{2l}} \times \left\{-\frac{rt}{l} I_1\left[\frac{-rt}{2l}\right] + \left[1 - \frac{rt}{l}\right] I_0\left[-\frac{rt}{2l}\right]\right\} + \frac{R_{HS}^4}{N^4}\,\frac{c^2}{l^2}\left(1 - \frac{rt}{l}\right)\epsilon^{\frac{-rt}{l}} + \quad (3)$$

In this equation I_0 and I_1 are hyperbolic Bessel functions.

Discussion

Charles J. Miller, Jr., and **John F. Wittibschlager** (The Ohio Brass Company, Barberton, Ohio): The author presents a very concise and clear analysis of the two types of errors which may be introduced by the use of a coaxial cable to connect the potential divider to the cathode-ray oscillograph.

The attenuation characteristics of a 100-foot 3-shield coaxial cable, with electrical characteristics similar to those of an *RG-11/U* 75-ohm cable were run in the Barberton High Voltage Laboratory of the Ohio Brass Company[1] using a technique very similar to that described by the author.

The results of this investigation are compared with those of the author in Fig. 8. This comparison indicates a close resemblance between the 3-shield cable tested and an *RG-8/U* cable. The somewhat higher attenuation of the *RG-11/U* over that of the *RG-8/U* at longer times to flashover is explained by its somewhat higher d-c resistance resulting from its somewhat smaller central conductor. At higher frequencies, on the other hand, the *RG-8/U* cable has approximately a 10% greater attenuation in decibels per 100 feet than does the *RG-11/U* cable, according to published catalogue data. This difference in attenuation would account for the *RG-11/U* curve crossing over the *RG-8/U* curve at shorter times to flashover.

Since the maximum deviation between the curves for the *RG-8/U* and *RG-11/U* cables represents a difference in attenuation of 0.6 of 1%, which is apparently explained by the geometric and electrical differences in the two cables, it would appear that the results obtained in the two different laboratories agree very well.

In the Barberton tests, the cable terminating resistance at the CRO plates was carefully matched for a time to flashover of about 0.08 μsec, using linearly rising chopped surges which were produced by the flashover of a 6-cm gap between 12.5-cm spheres. The principal elements of the arrangement are shown in Fig. 9. As indicated, the divider consists of a 1,000-ohm noninductive resistor R_1 and a 1-ohm noninductive resistor R_2, the details of which are described completely in a paper by the discussers.[1] The 3-shield coaxial cable is terminated by a noninductive resistor R_3 located at the CRO plates.

Resistor R_3 is made of a suitable length of Karma ribbon compressed in a zigzag fashion with two layers of 0.001-inch Mylar tape between adjacent layers. Both the coaxial cable and the terminating resistor R_3 are connected directly to the CRO plates with leads less than 1 inch long. A number of similar R_3 resistor units were made, each with a slightly different value of resistance about the 75-ohm level.

The results of the tests are shown by the oscillograms in Fig. 10. Note that only the lower voltage portion of each oscillogram has been reproduced. For the value of R_3 that terminates the coaxial cable properly for the 0.08-μsec pulse no reflected wave is set up, and hence there can be no voltage error due to improper matching. However, for other values of R_3, there will be a small reflected wave, the magnitude of which will depend upon the degree of mismatch, and thus a voltage error may exist at the CRO plates. This first reflected wave will travel to the input end of the cable where it encounters a very low impedance of about 1 ohm. A nearly equal wave of opposite polarity will be generated due to reflection, and this second wave will return to the CRO plates in about 0.3 μsec, the round-trip travel time in a 100-foot cable. Being of opposite polarity and nearly equal magnitude to the first reflected wave, it will nearly cancel the voltage error caused by the initial reflection. The return of the wave of opposite polarity will be detected by a sudden small change in the deflection of the oscillogram at about 0.3 μsec.

In Figs. 10(A) and 10(C), the voltage pips are due to a mismatch between the terminating resistance R_3 and the cable surge impedance, while Fig. 10(B) shows no such pip since the terminating resistance of 74.7 ohms provides the proper value for matching the cable surge impedance for the applied 0.08-μsec pulse.

As a matter of interest, the pips in Figs. 10(D) are due to the use of a commercially available noninductive resistor which has approximately the same d-c resistance as that used to obtain Fig. 10(B). The pips are probably due to mismatch caused by the residual inductance in this resistor.

The author points out that if the coaxial cable is terminated in that value of resistance which provides proper matching for a $1^1/_2 \times 40$-μsec wave, it will be somewhat in error for waves that crest in times shorter than 0.2 μsec, due to a slight reduction in cable surge impedance for these shorter waves, and hence a mismatch of terminating resistance. To avoid this difficulty, he proposes the use of a terminating impedance consisting of a 200-foot extension of the coaxial cable past the CRO plates, with a terminating resistance which matches properly for long times to flashover. However, the series resistance of the 200-foot cable extension introduces additional complications, as pointed out by the author.

It is believed that using a terminating resistor at the CRO plates which matches the surge impedance of the cable for short times to flashover will not introduce appreciable error for waves which reach crest values at times in excess of the round-trip travel time in the cable itself, provided the low-voltage resistance R_2 of the potential is small compared to the surge impedance of the cable.

As discussed in the foregoing, the return of an opposite polarity wave at the round-trip travel time in the cable nearly wipes out the voltage error created by the mismatch between cable surge impedance and terminating resistor R_3. Any residual error

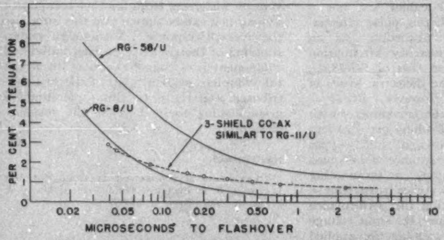

Fig. 8. Comparison of attenuation characteristics of 50-foot lengths of coaxial cables on linearly rising chopped surges

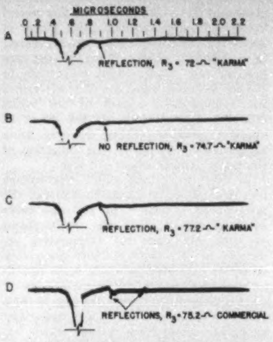

Fig. 10. Oscillograms showing effect of various terminating resistors at CRO plates

that may exist will certainly be reduced still more after a second round in the cable. By the time a $1^1/_2 \times 40$-µsec wave reaches its crest value, the error due to mismatch must be negligibly small.

This leaves the possibility of error for pulses which reach their crest value between the time for which the terminating resistor R_3 is properly matched and the round-trip travel time in the cable, which in the example given is from 0.08 to 0.30 µsec. However, when we remember that for 0.08-µsec pulses the cable is properly terminated, and as the author points out the change of surge impedance from full wave to 0.05-µsec wave is only about 2 ohms out of 50 ohms, or about 4%, the magnitude of the mismatch at 0.30 cannot be very large, and hence the errors in this range must be quite small.

There is also the possibility of error due to mismatch for pulses which reach their crest value at times shorter than that for which the cable is properly terminated. Here again, the error may be quite small since the surge impedance of the cable probably does not change too much for pulses between 0.05 and 0.08 µsec.

The terminating resistance at the CRO plates offers a practical advantage that is not available with the extended cable method of termination, and that is the possibility of a potential tap in order to provide a suitable level of voltage for the CRO plates without having to change the divider ratio. Such a resistor with a 0.4 tap was made in Barberton, using the zigzag Karma ribbon resistor, and tests on this potentiometer indicated that it gave accurate voltage division in accordance with its measured ratio. As it is designed as a plug-in unit, lead lengths can be extremely short, and it is possible to have an assortment of ratios which will provide convenient CRO deflections for a wide range of input voltages.

1. Measurements of Steep-Front Impulse Waves with an Isolated Screen Room Installation, **C. J. Miller, Jr., J. F. Wittibschlager.** *AIEE Transactions*, vol. 77, pt. I, July 1958, pp. 262–71.

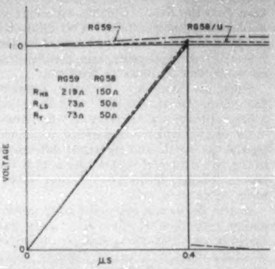

Fig. 11. Comparison of cable input voltages for 130-foot lengths of RG-59/U and RG-58/U terminating cables. Step function and steep-front waves applied

F. A. Fisher and **J. S. Kresge** (General Electric Company, Pittsfield, Mass.): Generally, when the transmission-line equations are solved, the effects of series resistance, shunt conductance, and skin effect are neglected. The resulting solutions then imply that the transmission line has a surge impedance independent of time and frequency, that there is no attenuation, and that a terminating resistance equal in magnitude to the surge impedance of the cable will prevent all reflections. This paper shows that none of these conclusions are strictly correct. Mr. Park discusses attenuation, waveshape distortion, determination of surge impedance, and terminating methods. We should like to bring up a few points on these same subjects.

Fig. 1 clearly shows the advantage of using *RG-8/U* cable instead of the smaller diameter *RG-58/U*. Practically without exception one can say that the small-diameter coaxial cables are unsatisfactory for pulse measurement use, unless they are used only in very short lengths. We have obtained similar data for *RG-11/U* and *RG-59/U*, which are the equivalent 75-ohm cables, and this also indicates that the small-diameter cable, *RG-59/U*, is not generally satisfactory.

It is important to realize that the radio-frequency attenuation figures normally published for coaxial cables are not a reliable guide for predicting pulse attenuation and waveshape distortion. As an example, the radio-frequency attenuation of *RG-59/U* is less than that of *RG-58/U*, presumably because the dielectric losses in *RG-59/U* are less. However, *RG-59/U* employs a copperweld center conductor with a d-c resistance of 5.5 ohms per 100 feet while *RG-58/U* employs a solid copper conductor with a d-c resistance of 1.4 ohms per 100 feet. Assuming a terminating cable length of 130 feet (twice travel time = 0.4 µsec) and calculating the performance by equation 1 of the paper, the input voltage of the two cables for a step function applied to the divider is as shown in Fig. 11. The values of R_{hs}, R_{ls}, and R_t were chosen to maintain the same over-all divider ratio. With *RG-59/U* cable the input voltage is 4% too high at 0.4 µsec; with *RG-58/U* cable it is 1.6% too high.

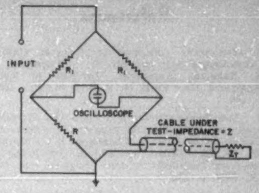

Fig. 12. Impulse bridge circuit for determining correct cable termination

Fig. 11 also shows the corresponding response to a linearly rising wave chopped abruptly to zero at crest time (steep-front wave) as calculated by the methods outlined in another paper.[1] Such a wave cresting at 0.4 µsec or less would be reproduced with an error of half that of the step function response at that time.

When determining the surge impedance of a transmission line or a cable the sensitivity may be improved by using a bridge circuit. Fig. 12 shows a diagram of a simple bridge which we have used. The resistors R_1 are taken approximately equal to the expected surge impedance. If R is adjusted for a balance at $t=0$ then the cable input impedance is equal to R. The correct terminating impedance is found by varying Z_t until no reflections at $t=$ twice travel time are seen. If such a bridge is constructed care should be taken to avoid errors caused by residual inductances and skin effect in the bridge elements.

Mr. Park uses a combination of a terminating cable and a fixed resistor to provide a termination correct for all frequencies. This can be done in other ways also; one simple way which we have found to be quite effective is shown in Fig. 13. R and C may be adjusted experimentally until reflections are minimized.

Finally, it should be noted that an incorrectly terminated signal cable may compensate for errors introduced by some other component of the measurement system. In a complete impulse-voltage-measuring system we are primarily interested in the over-all response and it would be legitimate to introduce errors deliberately in one component that compensate for errors from another component as long as it can be shown that this improves the over-all response. A thorough understanding of the response of each individual component is of course necessary to adjust the complete system. Mr. Park has contributed materially to this understanding in publishing these data on the response of cables.

Reference

1. Transient Response of Impulse Voltage Dividers, **F. A. Fisher.** *AIEE Transactions*, vol. 77, pt. I, 1958 (*Paper no. 58-37*).

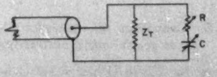

Fig. 13. Frequency-sensitive cable termination using adjustable trimmer elements

A. F. Rohlfs (General Electric Company, Pittsfield, Mass.): The influence that measuring cables may have on the accuracy of voltage divider systems has received much less attention over the years than have the other parts of divider systems. Mr. Park's paper on this subject should be most welcome to those people using or studying divider systems.

In the appendix of the paper a rigorous mathematical solution to the problem is developed. The resulting expression, however, is quite complicated. By using a traveling-wave approach with same approximations a simple solution can be found.

Assume that the cable is made up of n small elements each having a lumped series resistance r as shown at the top of Fig. 14.

The transmission coefficient for each element will be

$$A=\frac{2Z}{r+2Z} \tag{4}$$

and the reflection coefficient will be

$$B=\frac{r}{r+2Z} \tag{5}$$

The reflection coefficient at the input end of the cable will be

$$C=\frac{R_{LS}-Z}{R_{LS}+Z} \tag{6}$$

where R_{LS} is the terminating resistor at the input end. It is assumed that R_{LS} will be small compared to R_{HS}, the resistance of the high-voltage arm of the divider. The output end of the cable will be terminated with its surge impedance, Z.

A lattice diagram for a cable having a travel time T is shown in Fig. 14. The output voltage will be the sum of the components arriving at the right up to the time t under consideration. Thus

$$V_{\text{out}}=A^{(n-1)}+A^{(n-1)}[BC+(n-1)B^2]+ A^{(n+1)}[BC+(n-1)B^2]+\ldots+ A^{\{n-1+2(m-1)\}}[BC+(n-1)B^2]$$

$$V_{\text{out}}=A^{(n-1)}[1+[BC+(n-1)B^2]\times [1+A^2+A^4\ldots A^{2(m-1)}]]$$

$$V_{\text{out}}=A^{(n-1)}\left\{1+[BC+(n-1)B^2]\times \left[\frac{1-A^{2m}}{1-A^2}\right]\right\} \tag{7}$$

where

$$m=\frac{t-T}{2T}n \tag{8}$$

and

$$T\leq t\leq 3T \tag{9}$$

Now if m and n are of the order of 100 or less and $(1-A)$ is 0.001 or less,

$$A^n\cong 1-n(1-A)$$

and

$$A^{2m}=1-2m(1-A) \tag{10}$$

This will be the case for most practical cables in use with high-voltage dividers.

Substituting equation 10 in equation 7,

$$V_{\text{out}}=\{1-(n-1)(1-A)\}\times \{1+[BC+(n-1)B^2]m\} \tag{11}$$

From equatious 4 and 5

$$B=1-A \tag{12}$$

thus

$$V_{\text{out}}=\{1-(n-1)B\}\times \{1+[mBC+m(n-1)B^2]\} \tag{13}$$

For the conditions imposed in the foregoing on m, n, and $(1-A)$, the B^2 term will be small and can be neglected without appreciable error. If the lattice diagram were complete, it would also contain higher powers of B. However, these would be still smaller than the B^2 term and thus may be neglected. Therefore

$$V_{\text{out}}=[1-(n-1)B][1+mBC] \tag{14}$$

This can also be written

$$V_{\text{out}}=A(n-1)[1+mBC] \tag{14A}$$

The input voltage will be the sum of the components at the input end of the lattice diagram up to the time (t) under consideration.

$$V_{\text{in}}=1+B(1+C)(1+A^2+A^4\ldots+A^{2(k-1)})$$

Simplifying as before

$$V_{\text{in}}=1+KB(1+C) \tag{15}$$

where

$$K=\frac{t}{2T}n \tag{16}$$

and

$$0\leq t\leq 2T \tag{17}$$

Because of the approximations used, it is not possible to convert equation 15 into Park's equation 1 for the d-c solution. However, numerical substitution for several conditions to be discussed in the following shows that the equation 15 gives approximately the same answers as does Park's equation.

To illustrate the use of these equations let us assume that the resistance, R, of the cable is 11 ohms, $n=100$, $Z=55$ ohms, and $R_{LS}=5$ ohms, 55 ohms, and 1,000 ohms. Then $B=0.001$ and the input and output waves for the three values of R_{LS} will be shown in Fig. 15. A resistance of 11 ohms represents the resistance of 785 feet of *RG-58/V* cable.

Examination of these waves shows that the shape of the output wave will be true only when R_{LS} is equal to Z; however, the amplitude will be low. The shape of the wave at the input end will approach being correct when R_{LS} is small compared to Z.

Fig. 15. Voltage waves at input and output ends of cable for $R_{LS}=5$, 55, and 1,000 ohms

Table II. Input Voltage With 11 Ohms Resistance in Cable

R_{LS}	Input Voltage to Cable: Equation 15	Input Voltage to Cable: Equation 1 by Park
5	1.017	1.015
55	1.100	1.090
1,000	1.190	1.183

To compare equation 15 to Park's equation 1, it is necessary to have a complete divider. Therefore, let us assume that the divider ratio would be 1,000 to 1 if the resistance of the cable were zero. Then by equation 15 the input voltage with 11 ohms resistance in the cable will be as shown in Table II for 1,000 volts applied to the top end of the divider. Using values of R_{HS} that will give ratios of 1,000 to 1 and substituting in Park's equation, input voltage were also calculated.

The two methods agree fairly well.

Fig. 15 also indicates that the apparent attenuation of a measuring cable is dependent upon the value of R_{LS}. For example, in Fig. 15 the apparent attenuation is 2% for $R_{LS}=1{,}000$, 10% for $R_{LS}=55$, and 18% for $R_{LS}=5$. Thus one must take care that in applying a correction for "attenuation" the correction factor is determined for the actual values of R_{LS} in use.

This approach to the distortion of voltage waves by a cable does not consider the effect of frequency. In so far as higher frequencies cause an increase in cable resistance by means of a skin effect, the equation may be valid provided the proper resistance values are used. However, some of the increased "attenuation" at the higher frequencies may be due to dielectric loss and it is doubtful that such an effect could be handled in the same manner.

J. H. Park: I wish to thank the discussers for their contributions since they all enhance the value of the paper. While surge-voltage-measurement errors, introduced by the measuring cable, are normally quite low and nearly negligible for most laboratory tests, there appears to be considerable interest in methods for measuring such errors and correcting for them.

The method described by Mr. Miller and Mr. Wittibschlager for checking their cable termination resistor by using a steeply rising chopped wave is certainly satisfactory for their particular conditions. However, when the divider low side is much higher than 1 ohm (up to 50 ohms under some conditions) there will be no reflected wave from the low side to compensate for full-wave termination missmatch. A 100-foot terminating cable with full-wave matching resistor at its end, as described in the paper, can be used for all types of surges and all values of divider low-side resistance. By using *RG-8/U* cable the resistance of the 100-foot length used for termination is kept entirely negligible. Such a termination does not permit locating a resistance network at the CRO plates for adjusting sensitivity as used by Miller and Wittibschlager but experience at the National Bureau of Standards has indicated that such a network increases the likelihood of measurement errors due to stray magnetic fields from ground currents in the cable sheath. The magnitude of the deflection at the CRO can rather easily be controlled by using divider low-side resistors of different value.

The bridge circuit suggested by Mr. Fisher and Mr. Kresge (Fig. 12) to determine cable surge impedance would improve sensitivity if either (1) an amplifier is used in the CRO deflecting circuit or (2) an increased voltage is impressed on the cable. In either case, for steeply rising surges, it would appear that special precautions must be applied to eliminate pickup in the deflecting circuit because this circuit is not connected directly to ground. The suggestion by these discussers that errors due to cable termination may compensate for other errors would possibly work out under certain conditions. However, most errors are introduced by variables whose relation to other factors is not definitely known so that two sets of errors which compensate, say, for low-voltage impulse tests may not retain that relation under high-voltage conditions. The best procedure is to isolate errors wherever possible and apply corrective measures for each one individually.

The method presented by Mr. Rohlfs of taking cable resistance into account by using the traveling-wave lattice diagram is very interesting and contributes much to the paper. As indicated by him it is difficult, if not impossible, to work out a computation method which takes all factors, such as skin effect and dielectric losses, into account, and so an experimental check is always desirable. His computations show that cable attenuation as caused by its series resistance depends upon the particular values of resistance used in the divider. For this reason it is advisable to use as short a measuring cable as possible and one with a fairly large center conductor. This also emphasizes the importance of checking cable attenuation by the method described in the paper for the actual conditions of the test being used. The values given by the curves in Fig. 1 of the paper may be used as approximations with any value of divider low side but the divider low side should be between 5 and 10 ohms for a required accuracy of less than 2%.

The Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover Voltage

AIEE COMMITTEE REPORT

THE WORKING GROUP on Rain Tests was appointed in January 1957, for the purpose of studying problems associated with wet flashover and wet holding tests on high-voltage insulators such as are used on transmission and distribution lines. These problems are intimately concerned with the resistivity of the water used in the tests and the rate of precipitation with which it falls on the test specimen. In connection with the latter, a study of suitable methods for applying the water to the test specimen may well be an area for investigation, particularly for use in wet flashover or holding tests on extra high voltage insulation.

Present European standards for wet testing specify a water resistivity of 10,000 ohms/cm^3 (per centimeter cube) or 3,900 ohms/inch^3 and a precipitation rate of 3 millimeters/minute (0.118 inch/minute), while present American standards specify a water resistivity of 7,000 ohms/inch^3 and a precipitation rate of 0.2 inch/minute.

Wet flashover and wet holding voltages have been specified for practically all classes of high-voltage equipment including transmission and distribution line insulators, station bus insulators, switchgear, circuit breakers, bushings, and lightning arresters, both in America and in Europe. In each area, these values have been determined in terms of the applicable water resistivity and rate of precipitation standards.

In contemplating an international standard for rain tests, which would be applicable both in America and Europe,

---

Paper 58-27, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted October 15, 1957; made available for printing October 31, 1957.

The personnel of the Working Group on Rain Tests of the AIEE Subcommittee on Techniques for Dielectric Tests are C. J. Miller, Jr., *chairman*, T. L. Dyer, Jr., H. E. Fiegel, B. B. Kingsbury, and D. L. Whitehead. The material for this paper was accumulated mostly in 1938-1940 by the General Electric Company, The Ohio Brass Company, and the Westinghouse Electric Corporation.

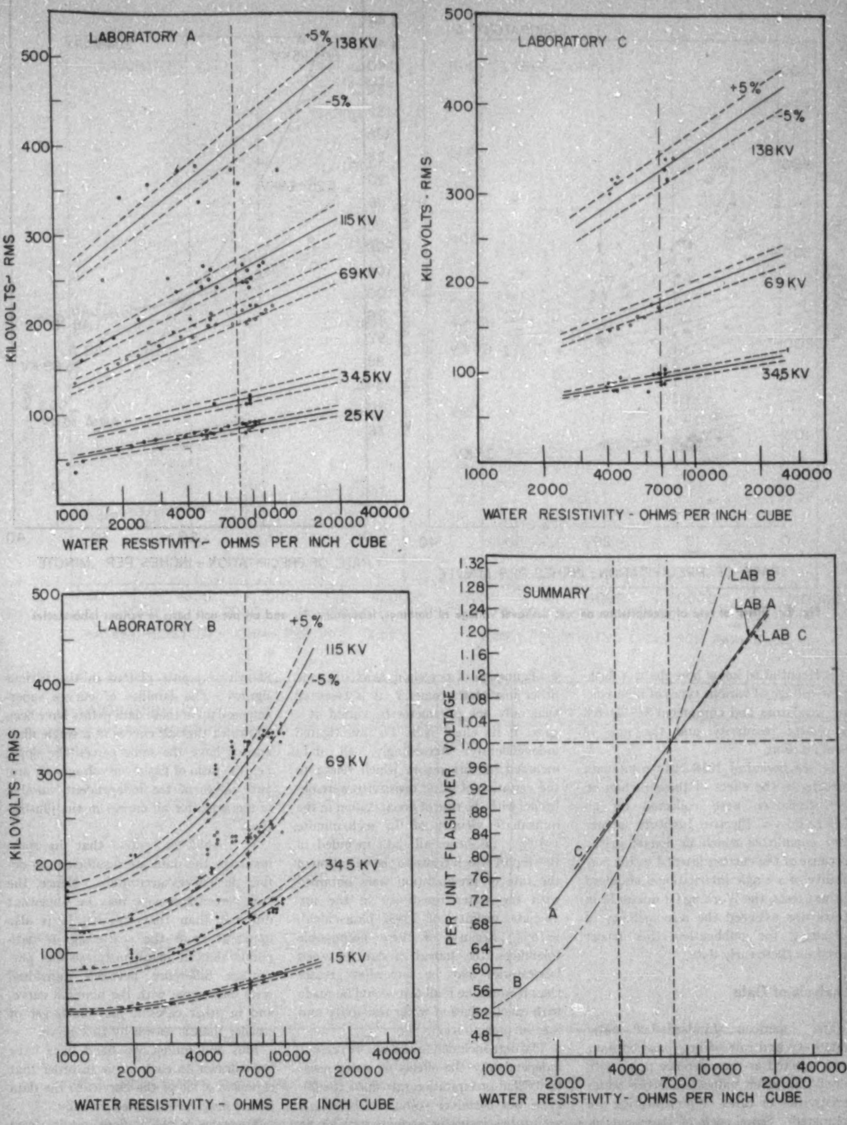

Fig. 1. Effect of water resistivity on wet flashover voltage of bushings in laboratories A, B, and C, and on per-unit basis in various laboratories, shown in summary form

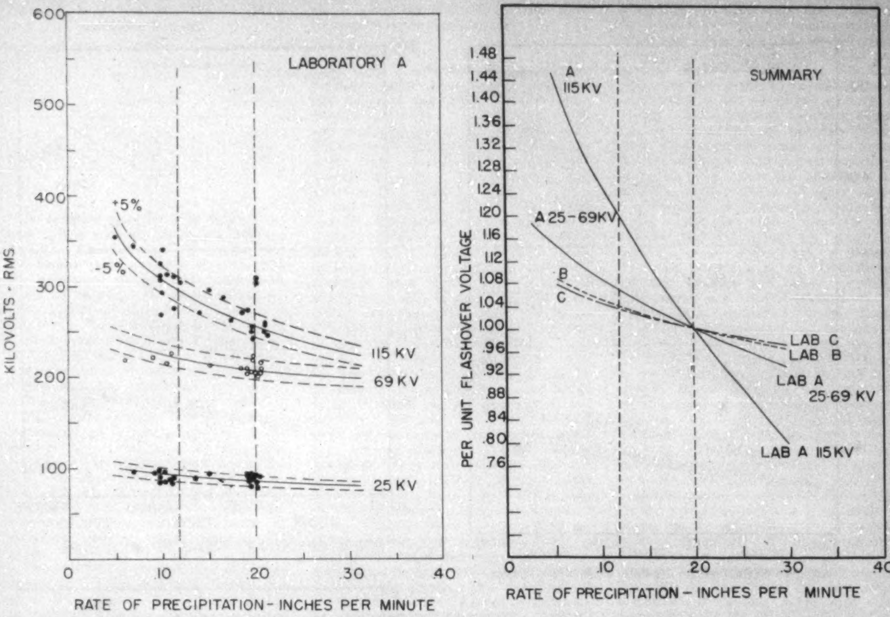

Fig. 2. Effect of rate of precipitation on wet flashover voltage of bushings, laboratory A; and on per-unit basis in various laboratories

it is essential to know how the wet flashover voltage of various types of high-voltate insulators and equipment is affected by water resistivity and the rate of precipitation.

In the period of 1938–1940 some data relating to the effect of these factors on wet flashover were collected by an AIEE–Edison Electric Institute laboratory committee which no longer exists. Because of the current interest in the possibility of a single international standard for wet tests, the Working Group on Rain Tests was assigned the responsibility of preparing for publication this report based on these early data.

Analysis of Data

The American standards of water resistivity and rate of precipitation have been selected as the reference point with which flashover values at other water resistivities or rates of precipitation are compared. Since each of these parameters has an effect upon the wet flashover voltage to a varying degree, depending on such factors as voltage rating, configuration of porcelain, skirt size, and other insulator geometry, it is essential that only one parameter be varied at a time, if its effect is to be investigated independently. Accordingly, all data included in this report which relate to the variation of water resistivity were obtained with the rate of precipitation in the immediate vicinity of 0.2 inch/minute ±10%. Likewise, all data included in this report which relate to the variation of the rate of precipitation were obtained with the water resistivity in the immediate vicinity of 7,000 ohms/inch^3, ±15%. Because of these permissible tolerances, the spread of data between laboratories may be somewhat greater than it would be if all tests could be made with exact values of water resistivity and rate of precipitation.

The data included in this report present independently the effects of water resistivity and precipitation rate upon the 60-cycle wet flashover voltage of bushings, suspension insulator strings, and single units such as pintype, switch, aud suspension insulators.

All of the actual test data included are shown as points plotted in the various figures. The families of curves superimposed upon these data points have been so drawn that all curves in a single illustration have the same percentage slope; i.e., the ratio of flashover voltages for any two values of the independent variable is the same for all curves in the illustration.

It should be noted that in some instances the data are insufficient to define the curves accurately. Hence, the true percentage slope may be somewhat different than that shown. It is also apparent from the scattering of data points that in many instances the percentage difference between individual tests may agree with the nominal curve, and in other cases it may be larger or smaller than is shown by this curve.

Plus and minus 5% band lines have been drawn on each curve in order that closeness of fit of the curves to the data points may be evaluated visually.

To compare the various results from the various laboratories with each other, and to show how the variable parameter influences wet flashover voltages, sum-

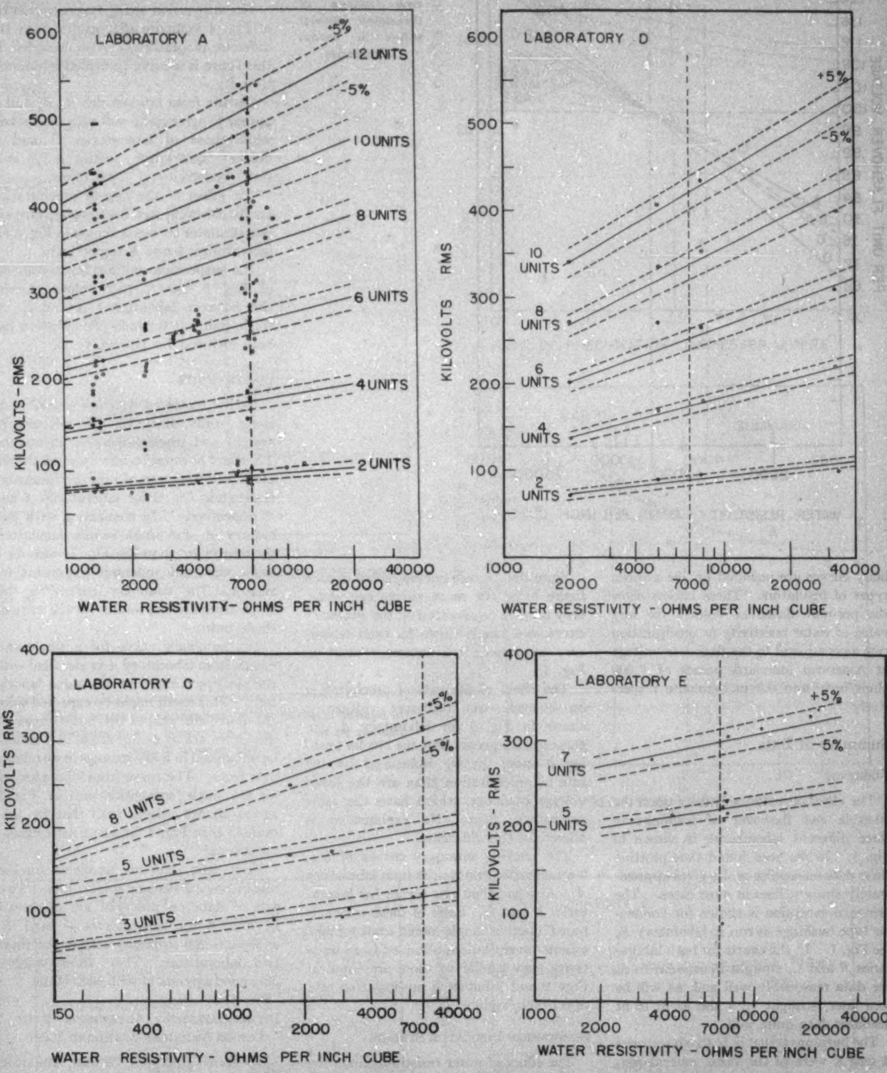

Fig. 3. Effect of water resistivity on wet flashover voltage of suspension insulator strings, laboratories A, C, D, and E

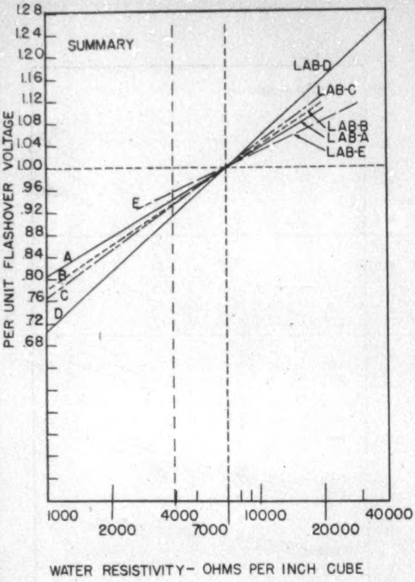

Fig. 4. Effect of water resistivity on per-unit wet flashover voltage of suspension insulator strings in various laboratories

mary curves are included for the various types of insulators. These curves show the per-unit flashover voltage for any value of water resistivity or precipitation rate as compared to the flashover voltage at American standard values of 7,000 ohms/inch^3 and 0.2 inch/minute respectively.

Summary of Data

Bushings

The effect of water resistivity upon the 60-cycle wet flashover of bushings in three different laboratories is shown in Fig. 1. It has been found that plotting these data on semilog scales gives approximately straight lines in most cases. The principal exception is shown for condenser type bushings as run in laboratory *B*; see Fig. 1. In the charts for both laboratories *B* and *C*, straight lines seem to fit the data reasonably well and, as will be seen later, straight lines also seem to fit insulator data quite well.

The bushings tested in both laboratories *A* and *C* were of the same general construction, being of the oil-filled type in which the insulation consisted of a number of concentric barriers of solid dielectric material with layers of oil between adjacent barriers.

Since the average curves shown in each figure have the same percentage slope, they may be represented on the summary curve as a single curve for each laboratory concerned; see summary chart in Fig. 1.

The effect of the rate of precipitation on 60-cycle wet flashover voltage is shown in Fig. 2 for laboratory *A*. In this case, it appears that the 115-kv bushing is more greatly influenced by the rate of precipitation than are the lower voltage bushings, which have the same percentage slope. No explanation is offered for this difference.

The bushing summary curves of Fig. 2 compare the two results from laboratory *A*. Also included are curves for laboratories *B* and *C*. Each of these curves is based upon a single point at 0.1 inch/minute precipitation, obtained from resistivity tests similar to those presented in Figs. 2 and 3 but at a precipitation rate of 0.1 inch/minute.

Suspension Insulator Strings

The effect of water resistivity upon the 60-cycle wet flashover of strings of suspension insulators in the vertical position is shown in Fig. 3 for laboratories *A*, *C*, *D*, and *E* respectively. In each case, the straight lines, which on the semilog plot appear to fit the data quite well, are so drawn that they have the same percentage slope.

The suspension string summary curves of Fig. 4 compare the results from the different laboratories. Also included in this figure is a curve furnished by laboratory *B*.

Results from laboratories *A*, *B*, and *C* appear to agree quite well with each other, while those of laboratories *D* and *E* bracket these curves within ±3% at a water resistivity of 4,000 ohms.

The effect of the rate of precipitation on the 60-cycle wet flashover of suspension insulator strings is shown in Fig. 5 for laboratories *A* and *E* respectively.

The suspension string summary curves of Fig. 5 show a very close correlation between laboratories *A* and *E*. A single point at 0.1-inch precipitation has been included for laboratory *C*.

Single Units

Rather scattered data are available on single units such as pintype, single-switch, and single-suspension insulators. The effect of water resistivity upon the 60-cycle wet flashover of pintype insulators is shown in Fig. 6 for laboratories *A* and *E* respectively. In connection with laboratory *A*, for single-switch insulators, the results are shown in Fig. 7; also for a single vertically mounted suspension insulator. The summary curves in this figure compare the results for the various single units.

The summary curve for a single-unit switch from laboratory *A* is identical with the pintype curve from the same laboratory. This result might be expected since the porcelain shapes on both types of insulators are so nearly alike, and should be influenced in a like manner in wet flashover tests. The curve from laboratory *A* for the single suspension unit in Fig. 7 agrees almost exactly with that for laboratory *D* in Fig. 4 for suspension insulator strings.

Very little data are available on the rate of precipitation on single units. Two sets of data on pintypes are presented in Fig. 8 for laboratories *A* and *E*, as well as the summary curves for these two laboratories. They show reasonably good agreement with each other.

Interlaboratory Agreement with Use of American Standard Rain

To show how well various American high-voltage laboratories agree when present American standards for rain testing are used, the wet flashover voltages for four different string lengths of suspension insulators, as obtained in four

different laboratories, are shown in Table I. Corresponding wet flashover voltages are given in Table II for four different apparatus insulator stacks as tested in three different laboratories. These tables indicate the maximum plus-and-minus per-cent deviation from the average of all laboratories, and the total per-cent spread in data.

Conclusions

The data included in this report cover only a few types of high-voltage insulators that may be used by the electrical industry. The present American standards for water resistivity and precipitation rate were established a number of years ago, and since that time considerable wet flashover and wet holding data have been gathered on all types of insulators and equipment using these standard conditions, and very little effort has been expended to determine the effects which departures from these values might have upon flashover voltage. Thus, the entire American practice of high-voltage engineering for transmission and distribution of electric power is intimately tied to the American standards for wet testing of insulators and equipment. With this thought in mind the following conclusions may be drawn with respect to the data presented:

1. Wet flashover tests on different types of insulators and bushings using water having the European standard resistivity of 10,000 ohms/cm^3 (3,940 ohms/inch^3), but with 0.2 inch/minute precipitation rate, give wet flashover voltages ranging from 0.77 to 0.96 of the voltage that is obtained when the water resistivity meets the American standard of 7,000 ohms/inch^3 and 0.2 inch/minute precipitation rate.

2. Wet flashover tests on different types of insulators and bushings having the European standard precipitation rate of 3 millimeters/minute (0.118 inch/minute), but with 7,000 ohms/inch^3 resistivity, give wet flashover voltages ranging from 1.03 to 1.20 of the voltage that is obtained when the water precipitation rate meets the American standard value of 0.2 inch/minute and 7,000 ohms/inch^3 resistivity.

3. All results presented in this report show the influence of varying only one quantity at a time, while keeping the other quantity fixed at the American standard value. Since the European standard specifies a lower resistivity, which tends to decrease the wet flashover voltage, and a lower precipitation rate, which tends to increase the wet flashover voltage, it is anticipated that the combined effect of changing both variables simultaneously from American to European standards would have less effect than changing either one alone.

In Table III, the per-unit value for each type of insulator for each laboratory has been taken from the corresponding summary curves for resistivity and precipitation. Only those values are included in this table where both resistivity and precipitation data are available from the same laboratory. The bottom row in Table III gives the product of the two per-unit values listed in the two rows above it, and presumably shows the net effect of changing from the American standards to the European standards of water resistivity and rate of precipitation.

The net result of this analysis seems to indicate that the two factors tend to offset each other for suspension and pintype insulators, but not for bushings.

4. The results presented in Table III, however, do not necessarily mean that European standards of water resistivity and precipitation rate could arbitrarily replace American standards without affecting presently established wet flashover and wet holding values on these types of insulators based on these standards. Very few tests have been conducted in which both parameters have been changed simultaneously to the European values, and hence it is believed that suitable correlation tests are necessary before any progress can be made toward the acceptance of a single international standard which may provide for water resistivity or precipitation rate different from present American standards.

5. Since only a few types of insulators have been included in this report, it is also believed that similar tests should be made on other types of insulators, as well as other types of high-voltage equipment, before attempting to agree on an international standard which provides for a different water resistivity or precipitation rate than are now specified in the American standards.

6. The excellent agreement shown in Tables I and II for 60-cycle wet flashover values obtained in various high-voltage laboratories, when American standards for water resistivity and rate of precipitation are used, indicate the adequacy of these standards, as well as their interpretation and application in these laboratories.

◆

Discussion

H. A. Frey (General Electric Company, Baltimore, Md.): As the committee points out in its timely report, it is apparent that more complete data are needed before a decision is made on the desirability of changing to the International Electrotechnical Commission (IEC) test method; and that the present American standard test does yield remarkably reproducible results when applied in different laboratories.

In considering wet flashover tests and wet withstand tests it must be remembered that their function is to provide standards of measurement which are controllable and reproducible from time to time and from one laboratory to another. They are not intended to be representative of service conditions.

The resistivity and rate of precipitation of natural rain are highly variable. The actual effective resistivity of natural rain on insulator surfaces will probably be more influenced by contamination on those surfaces than by the resistivity of the rain itself. Furthermore, the direction of natural rain may be vertical or at any angle from vertical, depending upon the wind. The size of rain drops may also vary over a wide range. All of these variables will materially influence the wet flashover voltage of insulators in practical service applications.

It is important that our standard tests be made under controlled and reproducible conditions. From such standardized measurements judgment and experience may be applied in establishing insulation which will perform satisfactorily under variable service conditions. If a change in the standards of measurement should result in differences in the standard test results, much of the experience of the past may be lost, unless reliable correction factors are known. It is therefore important that the effect of any change in standards be known before such change is made.

On the other hand, there are some potential gains to be made from a change to the proposed IEC standards for wet tests. The lower precipitation rate reduces the quantity of water which must be stored and disposed of in the laboratory. The lower resistivity may in many cases eliminate the need for preparing water of special resistivity for tests. In many communities the city water supply has a resistivity within tolerable range of the IEC standard of 3,900 ohms/inch^3. These advantages, plus the need for acceptable international standards, make a thorough study of the effect of the IEC method on the wet flashover voltage of various types of apparatus highly desirable.

C. J. Miller, Jr.: As Mr. Frey points out, wet testing standards are intended to provide a method of measurement which is controllable and reproducible from time to time and from one laboratory to another, and are not intended to be representative of service conditions.

It is perhaps unfortunate that American Standards Association (ASA) and IEC standards prescribe different rates of precipitation and water resistivity, and ultimately it is hoped that some means may be found to bring the two standards together.

Up to the present, very few tests have been run in which both rate of precipitation and water resistivity have been modified simultaneously from the ASA values to the IEC values. Accordingly, a tentative test program has been prepared by the AIEE Working Group on Rain Tests in which certain selected specimens representing a wide range of high-voltage apparatus are to be subjected to wet flashover tests under ASA conditions, IEC conditions, and a set of compromise conditions which provide for a water resistivity and rate of precipitation which are intermediate between those values specified by ASA and IEC. When these tests are completed, a single international rain test may be nearer than it appears at present.

An Analog Computer Study of the Transient Behavior and Stability Characteristics of Serial-Type Digital Data Systems

OLLE I. ELGERD
MEMBER AIEE

THE most significant change that has taken place in the field of control in recent years has been the appearance of the digital component. The ability of the digital computer to handle and process data quickly and accurately has been the main reason for incorporating digital devices into modern high-performance control systems. The exceptional requirements demanded from today's control systems in the defense area have prompted the development of a large variety of digital components for use in closed-loop control systems for defense applications.

The industry is right now in the process of incorporating many of these components in the industrial control field, and at the same time developing new components for exclusive use in special industrial applications.

This rapid increase in the employment of digital control techniques is forcing the control engineers to take a fresh look at the basic problems associated with this type of control system. The digital components introduce stability problems not encountered in continuous control systems, and special performance criteria apply. The present study is intended to augment the knowledge of digitized control systems. It has been considered of particular interest to investigate the influence of sampling rate on transient system behavior and stability.

The control system of which the digital component is a part can, at least in a first approximation, be considered linear and thus be represented by a transfer function, the complexity of which reflects the complexity of the system. The probability that two systems will have the same transfer functions is rather small, and one realizes therefore immediately the necessity of classifying different control systems into groups characterized by approximately equal performance data. Such a basis for classification has been introduced and made use of throughout the report.

From an analytical standpoint, the

Paper 58-31, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted August 29, 1957; made available for printing November 1, 1957.

Olle I. Elgerd is with the University of Florida, Gainesville, Fla.

This report summarizes the results of a study performed at the Advance Engineering Department of General Electric Division of Industry Control, Roanoke, Va. The author wishes to express his appreciation to Dr. F. M. Bailey for valuable suggestions and fruitful discussions.

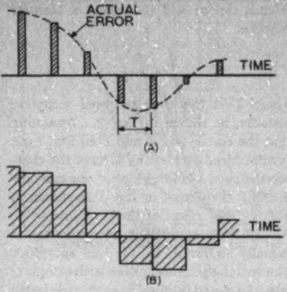

Fig. 2 (left). Graphs illustrating the error signal as it appears at different points in the control system

A—Graph (the envelope) of the actual continuous error as defined by $e(t)=r(t)-c(t)$. The upper train of pulses represents the input $e^*(t)$ to the holding circuit
B—Graph depicts the output from the holding circuit $e_o^*(t)$

digitizer represents a tremendous increase in the degree of computational difficulty. The reason for this is, of course, a consequence of the fact that while a continuous system is governed by a linear differential equation, the digitized system obeys a difference equation. As a result only the very simplest types of sampled-data systems will readily lend themselves to numerical investigations. The analyst has at least a number of time-saving techniques at his disposal. Truxal[1] gave in 1955 in his book a good résumé of the accumulated knowledge of sampled-data systems up to that time, and the field has not been subject to any earth-shaking news since then. Thus, the so-called *z*-transform as described by Ragazzini and Zadeh[3] in 1952 and "Linvill's Method"[8] represent the best analytical tools available today.

The *z*-transform is in a way quite limited in that it describes the control system in a discreet manner, i.e., it gives information about the output only at the sampling instants. This might in many cases be sufficient; in particular is this true when the sampling frequency is relatively high. Linvill's method on the other hand describes all signals as continuous time functions, i.e., it gives information about the system response for any value of time. It is generally known that whatever method is employed, an exorbitant amount of numerical labor is necessary in order to obtain the transient response for a sampled-data system characterized by some degree of complexity. This is very unfortunate and has had the quite understandable consequence that very little published information is presently available.

Objectives of Present Research

The purpose of this investigation is to augment our present knowledge of sampled-data system response. Particular stress has been placed on a study of the transient response to a standard input function (step input). The response has been investigated as a function of the sampling frequency and stability limits have been established in each particular case.

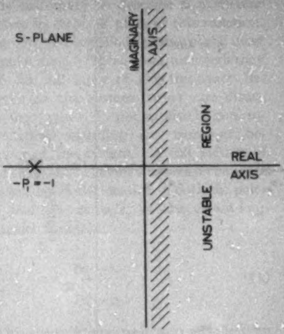

Fig. 5. Case 1: Closed-loop pole configuration

The investigation has been limited to serial-type digital data-handling systems. Considering the large variety of digital control systems in use, a study of present types must of necessity be limited in scope.

One of the main features of this report is its intended applicability of its many diagrams to other control systems. Indeed this was one of the main objectives when the present data were collected and organized. How this has been accomplished and how the diagrams should be interpreted will be covered in more detail later. It will at this time suffice to mention that a classification of different control systems has been made on the basis of location of closed-loop poles and zeros. It will be shown that this is the natural basis for classification and, indeed, the only possible one in a study of present generalized nature.

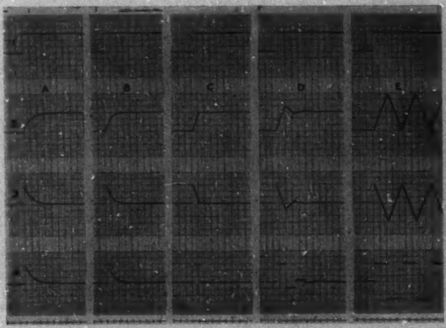

Fig. 6. Case 1: System response to a step input. Chart A depicts an unsampled system, B to E a sampled system. Sampling rate varied

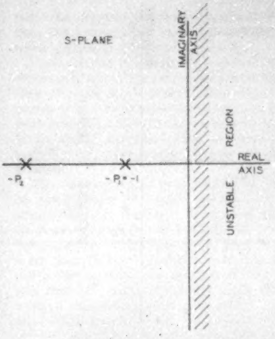

Fig. 7. Case 2: Closed-loop configuration

The afore-mentioned numerical difficulties have been circumvented by adopting analog-computer techniques. All the systems treated in this report were simulated on a Goodyear Electronic Differential Analyzer, and all the data in the report were obtained experimentally.

System Description

It should, from the outset, be clearly pointed out that this study concerns sampled-data systems incorporating a holding circuit. Fig. 1 depicts a prototype of the control system under investigation. The input, instead of being of the continuous type, as shown, can as well be digital, as is the case in programmed card controllers. It is obvious that quite a variety of control systems may be identified with the prototype in Fig. 1. One realizes immediately the necessity of defining at the outset the function of each of the system components. The practical value of the results obtained from a simulation of such a system is a function of how well the assumed operation agrees with the function of the actual hardware.

A large variety of mechanical and electric analog-to-digital converters are presently available.[4–6] They are all characterized by their ability to sample a continuous signal at preset discreet sampling instants. The combined operation of the components A, B, and D in Fig. 1 will thus be to sample the continuous input and output signal $r(t)$ and $c(t)$ at the same instants, compare them and then deliver an error signal consisting of equidistant pulses. In reality, these pulses will have finite duration, but it is general practice to assume that the duration is of infinitesimal duration. This pulsed-error signal is not of suitable wave form to actuate directly the rest of the system and, for this reason, it is fed into the digital-to-analog converter C. (It is worthwhile to mention that in many cases the components A, B, C, and D are physically indivisible.) The converter C is simply a pulse-shaping network, the purpose of which is to extract the usable information from the pulse train. As this information is hidden in the envelope of the pulse train, C must in effect be a low-pass filter. The ideal network should be able to anticipate during the interval between two pulses the magnitude of the next pulse, but as this is extremely difficult or maybe impossible to accomplish, the next best thing is to let the error signal in each interval equal the last preceding pulse. This arrangement is referred to as a holding circuit. Such a device will thus have a transfer function

$$\frac{1-e^{-sT}}{s}$$

where T is the time between sampling instants, as shown in Fig. 2. Assuming that the converters A and D in Fig. 1 are synchronized and letting C have the characteristics of a holding circuit one can now simplify the circuit in Fig. 1 as shown in Fig. 3. The effect of the components A, B, and D is equivalent of the switch S (usually referred to as the sampler). The switch opens and closes with sampling rate, the closed interval in each cycle being infinitesimally short.

Simulation Techniques

The simulation of the fixed linear part of the system in Fig. 3 does not impose any particular problems, but follows standard procedures.[7] It might be of interest, however, to describe in some detail the method employed in simulating the sampler plus the holding circuit. The circuit depicted in Fig. 4 was found to do a very satisfactory job.

It has the advantage of permitting us to use one of the computer amplifiers. If the error signal $e(t)$ is applied to the input, this circuit will deliver with very good accuracy the desired sampled signal $e_s^*(t)$ (with reversed sign). For proper functioning, the following conditions must be fulfilled.

1. The switch S must have a closing cycle similar to the sampler, i.e., it should be closed during a very short interval of the cycle.
2. The time-constant RC should be much

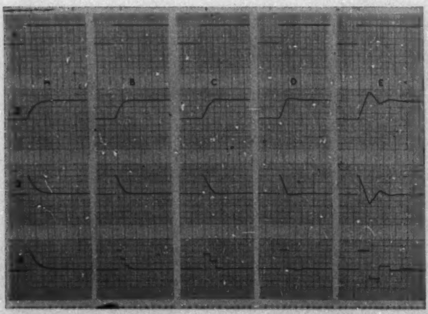

Fig. 8. Case 2: System response to a step input. Chart A depicts an unsampled system, B to E sampled systems. Sampling rate varied. $P_2=8$

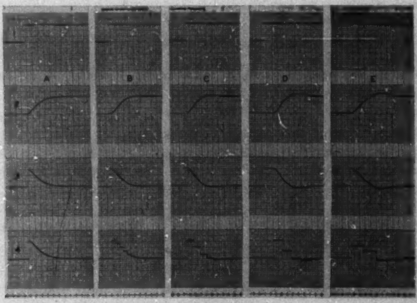

Fig. 9. Case 2: System response to a step input. Chart A depicts an unsampled system, B to E sampled systems. Sampling rate varied. $P_2=1$

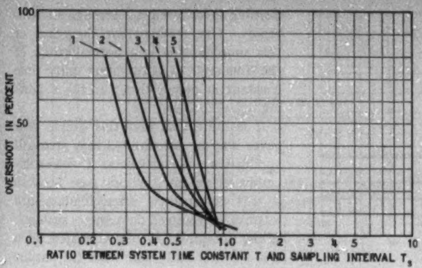

Fig. 10. Case 2: Overshoot versus sampling rate

The different plots apply to systems having:

1. $p_2=1$
2. $p_2=2$
3. $p_2=4$
4. $p_2=8$
5. $p_2=\infty$

less than any other time constants in the circuit in which it is operated.

If these conditions are fulfilled, the output voltage will, when S is closed, very quickly assume the same value as the input (with reversed sign). When S then opens, the output voltage due to the action of the capacitor will remain constant until S closes next time. The switch S was designed as a rotating commutator driven by a d-c motor thus permitting a convenient variation of the sampling frequency. It should be noted that the closing time of S must not be too short; the capacitor must be given ample time to assume its correct value of potential. Evidently this condition will restrict the sampling rate. The following parameter values were found suitable:

$R=0.01$ megohm
$C=0.5$ microfarad
Closing time of switch equals $^1/_{25}$ of period time T.

The preceding values give a time-constant of 5 milliseconds. If we require that the switch should be closed at least during 25 milliseconds, (this will allow the capacitor to charge up to 99.5% of the input voltage) the maximum permissible sampling rate will be:

$$\frac{1}{25(0.025)}=1.60 \text{ cycles per second}$$

A relatively slow computer time scale must therefore be chosen.

Classification of Control Systems on Basis of the Closed-Loop Pole and Zero Locations

This study is in effect a comparison of the response between a sampled and an unsampled or continuous system. It should be noted in passing that a continuous system can be considered to be a special case of a sampled system; one having infinite sampling frequency. As a continuous system is uniquely determined from its open-loop transfer function $G(s)$, it is customary to describe a particular system in terms of plots of this function. The Nyquist and Bode plots are the most popular ones. These plots, although they tell the full story of the frequency behavior of the system, suffer one disadvantage; they do not explicitly give information regarding the transient behavior of the system. A full picture of the transient behavior requires a complete knowledge of the location of both the poles p_ν and the zeros z_ν of the closed-loop transfer function:

$$\frac{G(s)}{1+G(s)}=K_c\frac{\overset{m}{\Pi}(s-z_\nu)}{\overset{n}{\Pi}(s-p_\nu)} \qquad (1)$$

(This study limits itself to true follow-up systems, i.e., systems having zero-position error for a step input. This means that

$$K_c=\frac{\overset{n}{\Pi}(-p_\nu)}{\Pi(-z_\nu)}$$

which may readily be verified by using the "final-value theorem.")

Once the z_ν; s and p_ν; s are known, it is possible to find immediately the transient response:

$$c(t)=\sum_{\nu=1}^{n}A_\nu\cdot e^{p_\nu t} \qquad (2)$$

The amplitudes A_ν are most easily expressed in terms of distances between the poles and zeros[8] or can be analytically

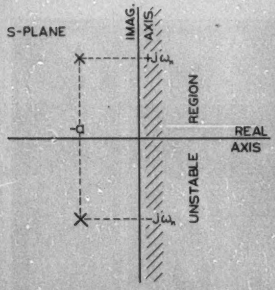

Fig. 11. Case 3: Closed-loop pole configuration

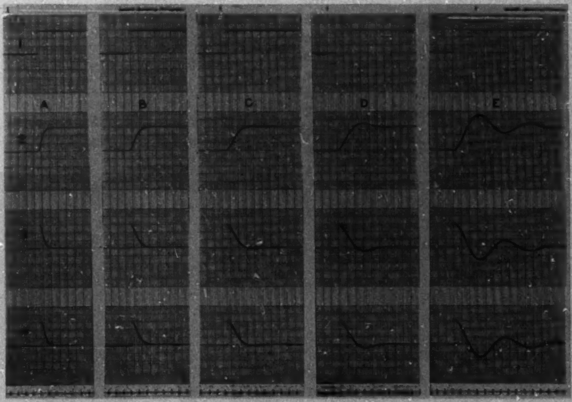

Fig. 12. Case 3: System response to a step Input. System unsampled

A. $a=4$
B. $a=2$
C. $a=1$
D. $a=0.6$
E. $a=0.2$

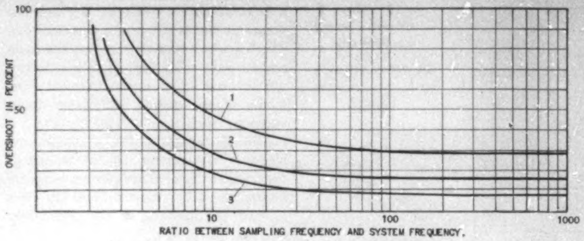

Fig. 13. Case 3: Overshoot versus sampling frequency

The three different plots refer to systems having:

1. a=0.4 2. a=0.6 3. a=0.8

determined by using Heavisides Expansion Theorem.

(The problem of finding the poles and zeros for a given system has been extensively treated by many authors.[9] It should be noted from equation 1 that the closed-loop zeros z_v coincide with the zeros at the open-loop transfer function $G(s)$ but the closed-loop poles p_v must be found by solving the characteristic equation

$$1+G(s)=0$$

This last task is comparatively simple if the powerful root-locus techniques are utilized.)

At a first glance it would seem to be a prodigious task to try to investigate every possible pole-zero combination, of which there exists an infinite number. Fortunately, most control systems, even the most complex ones, can be characterized by a very few poles and zeros, namely the ones located close to the origin in the complex s-plane.[9] We refer to those poles and zeros as the predominant ones. The reason for this predominance follows from equation 2, in which some of the A_v's will be very large compared to others. The actual transient response may thus be very accurately determined by taking only the large-amplitude terms into account.

Basis for Comparison of System Response

One of the classical control system problems is to find a criterion that will give information about the "best" system response. Several criteria have been proposed, for instance the relatively popular "error-square" criterion, but they all require explicit knowledge of the error as a function of time. Considering the fact that among control engineers there exists much doubt as to the relative value of these error criteria, it does not seem to be of any particular value to choose too sophisticated a basis for comparison. The choice has instead been governed by the desire to use a measuring rod which will allow quick reference. The overshoot of the system output serves this purpose well. Not only is the overshoot a measure of the relative stability but it gives the control engineer a good picture of the transient behavior of the system as well.

We will now proceed to investigate different systems characterized by increasingly complex closed-loop pole-zero configurations.

Case 1. Negative Real Pole, No Zero (Nonoscillatory Case). Fig. 5 depicts the simplest possible pole-zero configuration. In this case, the closed-loop transfer function can be written:

$$\frac{C(s)}{R(s)}=\frac{G(s)}{1+G(s)}=\frac{p_1}{s+p_1}=\frac{1}{s+1}$$

and thus:

$$G=\frac{1}{s}$$

(Note that no generality is lost by letting p_1 assume the value unity. This simplification is adhered to throughout this report. One realizes that the effect of this simplification is a normalization of the time scale so as to obtain unity time constant as demonstrated in the following.)

It is quite true that this simple case never may be encountered in a practical application. Nevertheless, it serves superbly as an introductory case because it will demonstrate some fundamental features of sampled-data servo systems. If the unsampled system is subject to a step input of unity amplitude the output will be:

$$c(t)=L^{-1}\left[\frac{1}{s}\cdot\frac{1}{1+s}\right]=1-e^{-t}$$

i.e., a purely nonoscillatory exponential response, as demonstrated in Fig. 6(A).

As to the charts in this report the following general remarks are made. From top to bottom the recordings show:

Channel 1.	System input $r(t)$
Channel 2.	System output $c(t)$
Channel 3.	Unsampled error signal $e(t)$
Channel 4.	Sampled error signal $e_s^*(t)$

In addition each graph contains at the lower edge a one-second time marker.

In Figs. 6(B) to 6(E), the system response is recorded for four different sampling frequencies. The following points of interest should be noted from those charts:

1. Although the system is inherently nonoscillatory, it will for sufficiently low sampling rate become oscillatory as evidenced by Fig. 6(D).
2. If the sampling rate is still decreased, the system will become unstable. Fig. 6(E) depicts the limit case.
3. For a certain sampling rate, the sampled-data system will have a more attractive response than the continuous system; the response of Fig. 6(C) is certainly to be preferred over Fig. 6(A).

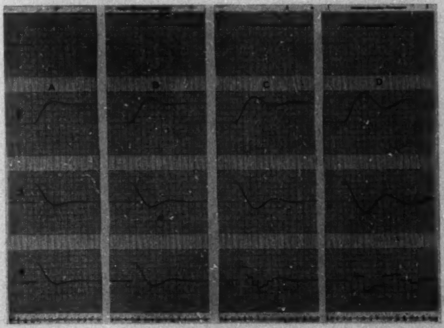

Fig. 14. Case 3: a = 0.6. The charts show the response to a step input if the sampling rate is varied

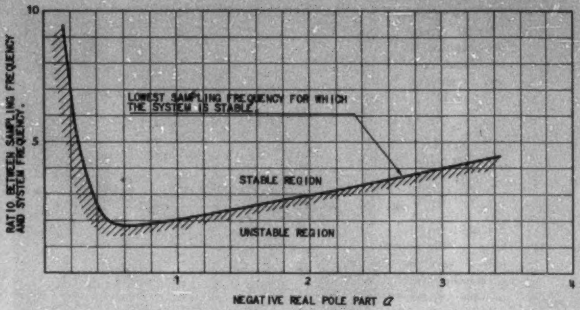

Fig. 15. Case 3: Minimum stable sampling rate versus damping factor a

The first two points apply to all control systems, the last one only to very sluggish ones.

In addition, the one-pole system is the only one where the output will consist of straight line segments.

Case 2. Two Negative Real Poles, No Zero (Nonoscillatory Case). This pole configuration is shown in Fig. 7. The system is characterized by:

$$\frac{G(s)}{1+G(s)}=\frac{p_2}{(s+1)(s+p_2)}$$

and thus:

$$G(s)=\frac{p_2}{s(s+1+p_2)}$$

The system response is built up by two monotonously decaying exponentials and the system is thus nonoscillatory. For increasing magnitude of p_2 this case approaches case 1 as a limit case. For large values of p_2 one can therefore expect a system response similar to the one in case 1. This is illustrated by the graphs of Fig. 8 which refer to a system having $p_2=8$.

For p_2 values slightly larger than unity, the system will in effect behave as if it had a double pole at $s=-1$. The double-pole behavior is demonstrated in Fig. 9, which clearly demonstrates the increased sluggishness. Charts *B*, *C*, *D*, and *E* of Figs. 8 and 9 show the response to a step input for sampled systems.

Fig. 10 finally gives in very condensed form information about the overshoot of the system as a function of the sampling rate. Because the system is inherently nonoscillatory, the sampling rate is expressed as a ratio T/T_s, where T is the largest time constant of the system ($T=1/p_1=1$ second) and T_s is the inverse of the sampling frequency f_s ($T_s=1/f_s$). The different plots refer to p_2 values in the complete range zero to infinity ($0-\infty$). Note that $p_2=\infty$ actually refers to case 1. The plots are interesting in that they reveal that it is possible to reduce the sampling frequency to a value of approximately $1/T$ cps before the system ceases to be nonoscillatory. For a further decrease in sampling frequency, the system turns oscillatory quite abruptly.

Case 3. Two Conjugate Complex Poles, No Zero (Damped Oscillatory Case). This case is very important because a large number of control systems are characterized by a (more or less) dominant complex pair of poles. The system is inherently oscillatory, the natural frequency of the system being ω_n radians per second (see Fig. 11), and the damping being expressed by the damping factor a.

In order to normalize, ω_n is set equal to unity and one then gets:

$$\frac{G(s)}{1+G(s)}=\frac{1+a^2}{(s+a+j)(s+a-j)}=\frac{1+a^2}{(s+a)^2+1}$$

and also:

$$G(s)=\frac{1+a^2}{s(s+2a)}$$

The sequence of charts in Fig. 12 demonstrates clearly what effect a variation of the real part of poles has on the system response. As the poles move to the right in the s-plane and thus approach the imaginary axis, the system gets more and more oscillatory. If the poles move far to the left, the system, although still oscillatory (not discernible on the chart), will approach the double-pole behavior shown earlier in Fig. 9(A).

If a is permitted to vary between 0.4–0.8, the overshoot of the unsampled system will vary between 29–8% and this might therefore be considered to represent the interesting region. The transient response of the sampled system was investigated for three different a values within the above range. The results of the study are condensed into the three curves in Fig. 13, showing the overshoot as a function of sampling frequency. The series of charts in Fig. 14 depict a typical run. (Note that the ratio of sampling frequency to system frequency is chosen as abscissa.)

The most significant information to be derived from these curves is that it takes

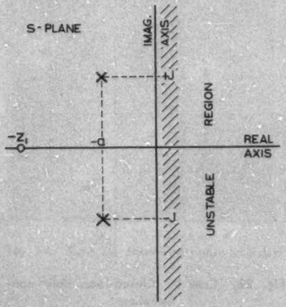

Fig. 16 (left). Case 4: Closed-loop pole-zero configuration

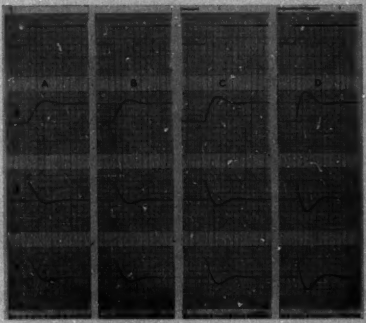

Fig. 17 (right). Case 4: System response to a step input. System unsampled. a=0.6

A. $z_1=4$
B. $z_1=2$
C. $z_1=1$
D. $z_1=0.6$

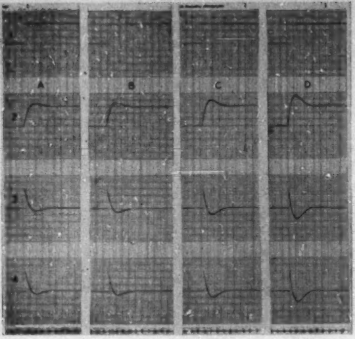

Fig. 18 (left). Case 4: System response to a step input. System sampled. a = 1

A. $z_1=1.2$
B. $z_1=1.0$
C. $z_1=0.8$
D. $z_1=0.6$

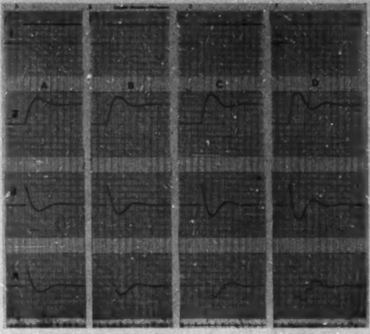

Fig. 19. (right) Case 4: The effect of variation of sampling rate on the system response. $a=0.6$, $z_1=1$

quite a high sampling frequency to preserve the desirable transient characteristics of a system. As an example: A system that unsampled has an overshoot of 15% will have a 40% higher overshoot for a sampling frequency of as high as 25 times the inherent system frequency.

To make the study complete, it was also investigated what effect the sampling has on the system stability. The procedure was to lower the sampling frequency until the system went unstable. The sampling frequency corresponding to this stability limit was plotted as a function of the negative real part a with the result shown in Fig. 15. One should observe the rapid rise below $a=0.5$.

Case 4. Two Conjugate Complex Poles, One Zero. This system, having the pole-zero configuration shown in Fig. 16, is characterized by:

$$\frac{G(s)}{1+G(s)}=\frac{1+a^2}{z_1}\cdot\frac{s+z_1}{(s+a)^2+1}$$

and

$$G(s)=\frac{1+a^2}{z_1}\cdot\frac{s+z_1}{s\left[s+\frac{2az_1-1-a^2}{z_1}\right]}$$

The effect of introducing the zero is most effectively demonstrated by the sequence of charts in Fig. 17, showing four recordings all made with a system having a fixed complex pole-pair ($a=0.6$) but where the zero occupies four different positions ($z_1=4$, 2, 1, and 0.6). When the zero is located far to the left the system approaches the one treated in case 3. This is confirmed by chart *A* which is almost identical to chart 12(D). If the zero moves to the right the rise time decreases, and we obviously obtain a faster system. This improvement will, however, be gained at the cost of a more oscillatory system.

It is interesting to note that by placing the poles relatively far to the left and the zero relatively far to the right one can obtain a rather attractive response. This is demonstrated by Fig. 18, which refers to a system having $a=1$. The four

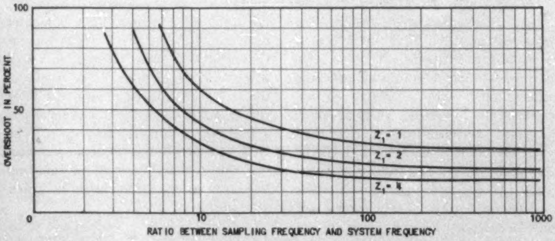

Fig. 20. Case 4: Overshoot versus sampling rate. $a=0.6$. The three plots refer to z_1-values as indicated in the figure

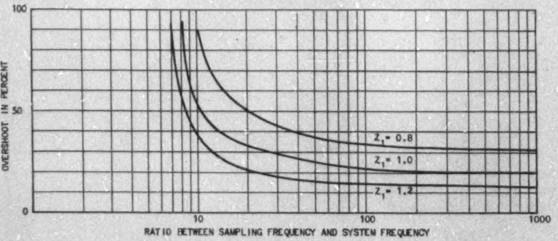

Fig. 21. Case 4: Overshoot versus sampling rate. $a=1.0$. The three plots refer to z_1-values as indicated

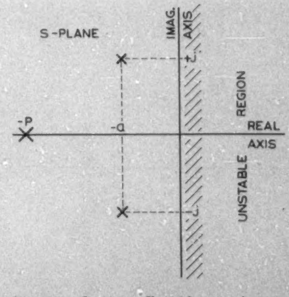

Fig. 22. Case 5: Closed-loop pole configuration

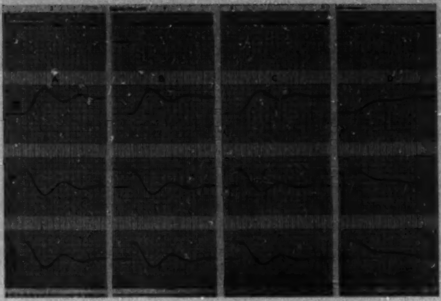

Fig. 23. Case 5: System response to a step input. $a=0.2$

A. $p=4$
B. $p=2$
C. $p=1$
D. $p=0.2$

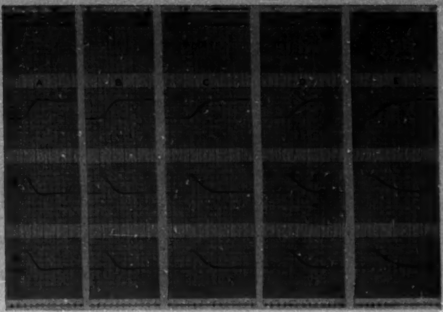

Fig. 25. Case 5: System response to a step input. $a=1.0$

A. $p=4$
B. $p=2$
C. $p=1$
D. $p=0.8$
E. $p=0.5$

charts are depicting the response for $z_1=1.2$, 1.0, 0.8, and 0.6. It should be noted that the location of the zero in this case is very critical; by putting it little too far to the right the system gets violently oscillatory.

If this system is made subject to sampling one must obviously expect more severe stability problems than in case 3. The four charts in Fig. 19 demonstrate this for a system characterized by $a=0.6$ and $z_1=1$. One can easily notice the tendency for large overshoot (and impaired stability) even for relatively high sampling frequencies. Even more revealing in this respect are the diagrams in Figs. 20 and 21. In Fig. 20 the overshoot is plotted versus sampling frequency for a system characterized bv $a=0.6$ and $z_1=1,2$ and 4. Fig. 21 refers to a system having $a=1$ and $z_1=0.8$, 1.0 and 1.2.

Case 5. Two Conjugate Complex and One Negative Real Pole. An additional pole positioned along the negative real axis as shown in Fig. 22 adds one more exponential term to the time response. The system is characterized by:

$$\frac{G(s)}{1+G(s)}=\frac{p(1+a^2)}{(s+p)\cdot[(s+a)^2+1]}$$

and

$$G(s)=\frac{p(1+a^2)}{s[s^2+(p+2a)s+1+a^2+2ap]}$$

This additional pole has the opposite effect as had the added zero in case 4; it will make the system slower and also more stable. The charts in Figs. 23, 24, 25 demonstrate this for three different locations of the complex pole-pair ($a=0.2$, 0.6, and 1.0). One can notice the decrease in overshoot and increase in rise time as the real pole moves to the right. Should the pole move too far to the right in the s-plane the system response will be intolerably slow; see for instance chart 23(D).

This stabilizing effect will also be felt in a sampled case-5 system. Fig. 26 depicts a typical computer run, from which one easily realizes the inherent stability of the system even for very low sampling frequencies. Fig. 27 finally shows how the overshoot varies as a function of sampling frequency for four different representative pole configurations.

Conclusions

The present report contains results from an investigation of the transient characteristics of sampled-data system. The

3. $a=0.6$ $p=2$
4. $a=0.4$ $p=2$

presented data have been found experimentally from simulation of the studied systems on a differential analyzer. In order to optimize the generality of this study and thus make the results applicable to other systems than the specific ones studied herein the main problem from the outset was to classify the systems in an orderly and logical fashion. The author makes no claim of a complete success of this aim but the idea of using the closed-loop zero and pole locations as a basis for classification is indeed both simple and promising and to the author's opinion outclasses any other thinkable basis for a classification.

The method is based on the fact that the large majority of control systems are fundamentally characterized by only a few of its many poles and zeros. Those predominant closed-loop poles and zeros are the ones located closest to the origin in the complex s-plane. Five different basic-pole zero configurations have been included in this study. Transient response and particularly the influence of sampling rate on system stability have been studied.

It is anticipated that the data made available in this report will be easily digested by the increasing number of control engineers who utilize the powerful root-locus design techniques.

Although the results are not directly applicable to systems for which only the frequency response is known (for instance in the form of a Bode plot) they still can be made useful as follows:

1. Correlate the Bode plot of the system under study with the transfer functions as given in each of the foregoing five cases. By a straight-line approximation within the frequency range of importance find out what the break frequencies are and also the slope between those frequencies (expressed for instance in decibles per octave). Choose then the case that agrees with the given system. Note, the preceding statement that some of the closed-loop poles and zeros of a system are predominant corresponds to the equally true statement that only the lower region of the frequency response need to be considered when the system response is discussed.

2 Vary then the system parameters (a, z_1, etc.) so that the given Bode plot approximately coincides with the Bode plot of the case that has been chosen.

Discussion

G. Farmanfarma and **F. Mullin** (University of California, Berkeley, Calif.): This paper is a good addition to the present literature in the field of sampled-data systems. Its objectives are carefully stated and carried out. These experimental results provide a clear picture of the transient behavior of sampled-data systems as their sampling rates are varied.

Although the word "earthshaking" may be individually interpreted, we do feel there has been significant contributions in this field since 1955 which should be added to the list of references. The addition of the modified z-transform[1,2] provides a technique for computing the response of sampled-data systems as a continuous function of time. Thus, all of the results presented in this paper are obtainable analytically.

The effect of the sampling period on the transient behavior of sampled-data systems has been mentioned by some authors.[3–7] In reference 6 a sampling rate has been specifically chosen to give a dead-beat response. Furthermore, in this reference the modified z-transform has been used to assure a continuous dead beat response; i.e., a response which is equal to the input for all values of time greater than the specified rise time. Also, we would like to point out that a similar computer study has been carried out in reference 4. However, we feel that many people will find the present paper helpful in the study of sampled-data systems.

Philosophy of Applying Digital Computers to the Design of Electric Apparatus

P. A. ABETTI

S. B. WILLIAMS
ASSOCIATE MEMBER AIEE

ONE DEFINITION of the word "philosophy" given by Webster's dictionary is "the body of principles underlying a given branch of learning or major discipline." In this paper the authors attempt to establish the philosophy, according to this definition, of applying digital computers to the design of electric apparatus. Although the authors' experience has been mainly in the field of power transformers, special-purpose transformers, and current-limiting reactors, they have followed closely similar applications to other types of electric apparatus, notably distribution transformers, medium transformers, and rotating machines. Because of this, and in view of the unity of the science and art of electrical design, it is felt that the concepts and conclusions developed in the paper will be generally valid for the broad class of electric apparatus.

An electric machine may be visualized as the site of several superimposed fields, namely, an electric field, a magnetic field, a current field, a field of mechanical forces, a field of conductive and radiated heat flow, a field of elastic forces in the material stressed by magnetic forces, and a field of fluid flow of the cooling medium. These fields must be considered from the steady-state and also from the transient point of view, since practically all machines are subjected more or less frequently to abnormal overstresses, in addition to the normal service stresses. The designer's problem is to analyze and modify these closely interrelated fields so as to translate the specifications into constructional features and data, with the ultimate aims of safety, simplicity, efficiency, and economy. The design of electric apparatus is both a science and an art: a science because it follows established and universally accepted physical and mathematical principles which have been verified by the experimental method; and an art in that knowledge of these principles is often insufficient to produce a correct and economic design, and must be supplemented by considerable judgment and experience which can be acquired only after intensive training on the job. This is due to: 1. the complexity of interrelations appearing in the design process, and 2. the lack of specific knowledge in certain areas which are continuously affected by new technological developments. The application of digital computers to the solution of mathematical, engineering, and data-processing problems may also be considered as both a science and an art for the same reasons.

Both electrical design and computer applications are quite new among the applied sciences. Electrical design is hardly 75 years old, since it followed the discovery of the rotating electric machine and of the transformer in the latter part of the last century. Digital computers, as is well known, were developed for military purposes toward the end of World War II, and only later were applied to nonmilitary computations. Starting less than 10 years ago, digital computers were first applied to the solution of individual mathematical problems arising from the design of electric machines; for instance, the solution of differential equations, the inversion of matrices, the calculation of mechanical stresses in a component, etc. These applications were limited to specific portions or phases of the design problem, which were particularly laborious, urgent, or difficult. Although extremely valuable in practice, these limited applications cannot be defined as electrical design in the broad sense given in the foregoing.

The marriage of the still young electrical design art and the infant digital computer art took place about 5 years ago. At that time, two of the authors applied the IBM (International Business Machines Corporation) card-programmed calculator (CPC) to the entire design process and, by an automatically convergent iterative procedure, were able to determine the constructional features which would meet the specifications.[1,2] The first power transformer designed in this manner came out of the Schenectady CPC in May 1953. Similarly, the application of computers to the design of rotating machines was first discussed in 1954.[3] Since that time, several papers have been written in this country on the subject of applying computers to electrical design, and work is actively progressing in this new and promising field.[4–9] The widespread use of digital computers for scientific, engineering, and data-processing applications in Europe has lagged behind that in the United States. In 1956, a paper[10] on the use of computers for power transformer design was published in Great Britain, which has been ahead of other European countries in the computer field. In a recent trip to Europe, one of the authors found that Swedish, French, German, Belgian, and Italian manufacturers of electric apparatus are investigating or using the digital computer as a design tool, and were well aware of its potentialities and advantages.

Thus, while the science and art of designing electric apparatus with digital computers is still in its infancy, it has, to date, achieved noteworthy practical results and is forging ahead rapidly, in this country and abroad. Therefore it appears opportune at this time to summarize the available knowledge and experience, and to establish a philosophy which may be used as a guide for future developments and applications.

It might appear more logical to establish first a philosophy, and then to apply it. But it is an outstanding characteristic of the American people, and particularly of engineers, that they want to go into action as soon as possible with practical work without worrying too much in this first stage about theoretical agreement on broad principles, philosophical niceties or details, etc. This is the characteristic of a growing, optimistic, aggressive society, goal-oriented rather than principle-oriented. However, sooner or later the time comes to organize resources and systematize knowledge in order to avoid excessive empiricism, lack of direction, and waste of manpower, time, money, and effort.

In this paper the purpose, the principles, and the process of design in electric apparatus will first be reviewed. Then, the characteristics of the modern digital computer will be reviewed. After this, the principles of applying the digital computer to electrical design according to

Paper 58-233, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 16, 1957; made available for printing November 20, 1957.

P. A. Abetti, W. J. Cuthbertson, and S. B. Williams are with the General Electric Company, Pittsfield, Mass.

the four steps of design analysis, design synthesis, optimization, and standardization will be developed at length. Wherever possible, examples, taken from the authors' experience, will be given of the practical application of these principles.

Design

Purpose

In its broadest sense, design entails the translation of specifications into information which describes the apparatus in the necessary detail and its performance. Its purpose, then, is to create an apparatus which will satisfy all of the desired specifications; conform to all applicable industry and company standards; be pleasing in appearance; and use all the materials within it and the applied labor, in the most economical fashion. In industry today there are many reasons why a particular design may be required and thousands of designers are employed to meet the needs. A design may be necessary to accomplish the following:

1. Set up a product line, which will satisfy the specifications and characteristics required by the majority of prospective users, as determined by detailed surveys of customers' preferences.

2. Assist a prospective customer in planning an installation. This type of design is usually made from sketchy specifications and can be quite approximate.

3. Estimate the physical characteristics and the cost of an apparatus so that the manufacturer may bid against competitors in the market place. When the specifications are exacting and when some very special characteristic is involved, a fairly detailed design may be required before the manufacturer can be sure of building the apparatus at reasonable cost.

4. Satisfy one rating of a line of standard units. Here the design problem differs from the custom-made apparatus in that many designs are made before an order is received in accordance with industry standards. Families of designs using duplicate components whenever possible and all having the same general appearance are usually found here.

5. Study the effect of using new materials, and of applying new technological developments.

6. Study the effect of new manufacturing tools or techniques.

7. Study the economics of changing the number or variety of "building block" components, in order to optimize practices.

8. Study the effect of changing the specifications of an entire product line, or the standards, on the cost and performance.

Principles

Engineers in an established product business with many years of available design knowledge do not often think of the principles which guide them in their design work. Nevertheless such principles exist; without them it would be impossible to design successfully. Engineers in a new product business are searching for principles, which often are not determined quickly or easily.

The principles of design are those factors, technical, practical, or esthetic, which guide designers in the setting up of design practices and in the making of design decisions. Some of these may apply only to a particular product; others may be quite general and may apply to broad families of products. The designer on the basis of his knowledge of electrical engineering fundamentals must understand the relationships between the design variables, such as flux density and current density, and the performance of the apparatus. He must be aware of the effect of variable loading on the efficiency of the apparatus: the effect of design geometry on the economics of material utilization. The designer must know the tools which exist in his factory, their capabilities and limits. He must be able to visualize the physical appearance of his apparatus before it is built. The customer must be continually kept in mind and his operating and maintenance problems adequately provided for. A sufficient number of safety factors must be built into the apparatus to prevent failure in service on overload or during abnormal conditions. The designer must be familiar with all industry standards which can affect the design of his particular apparatus and should display leadership in suggesting new standards which will benefit his customers and the industry in general. Especially for an established product business, such as transformers and rotating machines, the principles and rules of design are usually available to the designer in a "standard-practice" book, which lists the formulas and structures to be used, the standards to be met, the available tools in the factory, and other useful information. Standard practice is being continuously improved as a result of new technological developments, new standards, new ideas, and changing market requirements.

Regardless of the type of apparatus he is responsible for, the designer's frontiers are limited by the lack of sufficient technical knowledge, his inability to visualize simultaneously the interrelationships of all design variables, and the inadequacy of cost data. He is never quite sure to what extent a particular material should be stressed or what are the economics of changing a particular design feature. He is part scientist, part artist, continually balancing his technical knowledge with good judgment, making decision after decision, and calculation after calculation, as he moves along the design process.

Process

Once the principles of design are known and clearly understood by the designer, he may be given a set of specifications and told to prepare a design. The design process might be defined as the step-by-step attempt to satisfy the purpose of design by using the principles of design. The design process may take several forms. If the apparatus is simple, with few variables, it may be possible to construct a chart or nomogram which relates all the variables to the performance so that once the desired performance is known, values of the design variables may be immediately determined. Unfortunately, few products are so easily designed.

In the more normal case there are many design variables, some continuous, others discrete. The relationships between the variables and performance are usually nonlinear and the variables may sometimes be buried in complicated mathematical expressions such as transcendental functions, Fourier series, etc. There are usually more unknown independent variables than there are performance criteria so that any number of designs may be made to satisfy the specifications. The problem is, then, if time is available, not only to find one solution which will satisfy the specifications, but also to find the best solution. Hundreds of design rules may exist, all of which must be satisfied for proper performance and to ensure that the design being made is economical. Some of the components or building blocks to be used in the design may be completely fixed and only a few of them available. To synthesize such a complicated matrix of continuous and discrete variables into a rigorous, intelligible design process is a herculean task.

Fig. 1 shows schematically the process of design and the flow of information. The design process may be split into three parts: 1. The preliminary design, which is usually sufficient for a proposition, a design study, and the start of a requisition. 2. The final design, which is essentially the refinement of the preliminary design to the most minute and complete details. Its output is the final design engineering record and the drafting ond manufacuring instructions. 3. Checking of the final design, usually by another designer.

As shown in Fig. 1, both the preliminary and final designs draw heavily on the information contained in the standard-practice book and only seldom, in unusual cases, particular problems must be solved for which the information is not available. In this case the experts will be consulted. These are the more experienced designers, development engineers, and specialists in electrical, mechanical, and thermal problems. The standard-practice book embodies the best knowledge available in the design office and is being continuously revised, updated, and improved by the experts. In conclusion, with this system, during the design process the designer is very seldom called upon to solve complex mathematical equations, to analyze fields, to invert matrices, etc. In most cases these steps have already been taken for him by the experts, and the information is available in the standard-practice book in the form of tables, charts, nomograms, and predesigned structures and components. Thus, his job is to perform rather simple but lengthy calculations, usually with a slide rule, and to select, apply, and integrate the available information. In many ways, in addition to engineering calculations, he is doing engineering data-processing work. This point is important and will come up again later in discussing the type of computer to be used for design.

The time-honored design process for most apparatus is the cut-and-try method. The designer estimates values for all of the independent design variables, calculates the physical dimensions of all the components of the apparatus and then, for certain loading conditions, calculates its performance, such as losses, regulation, and temperature rises. These are compared with the desired performance. If the calculated values differ from those desired, the designer estimates in what direction and to what extent the independent variables should be changed, and repeats the calculations. This process is continued until the calculated performance is within acceptable limits of the desired performance. The length of time required to converge a design in this manner depends largely on the experience and ability of the designer. An inexperienced man will often discover to his chagrin that changes in values of the independent variables have resulted in a design which is further from desired performance than the previous design. The number of steps which the designer must take as he moves along the design process depends not only on the complexity of the apparatus but also how near he is to satisfying the required performance. Usually on the first couple of iterations the designer will make many approximations and avoid detail as much as possible. As the design "homes in" it is necessary to describe components in more detail and make more comprehensive and accurate performance calculations. This latter state may entail thousands of small steps such as selecting particular pieces of design information, integrating these with other pieces of information, calculating physical size, checking all design information to ensure that it is still adequate, and calculating performance. The designer may sometimes make sketches of circuits and components at this latter stage. When he is reasonably certain that the design is what he wants, he will write out the design output documents which contain all of the important information.

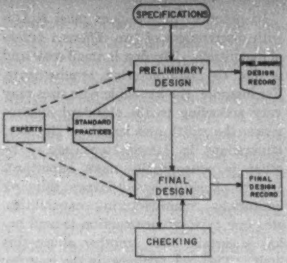

Fig. 1. Design process and flow of information

— normal flow
– – occasional flow

Most persons who have become genuinely interested in the design of electric apparatus have probably at some time in their careers been tempted by the idea of trying to synthesize manually the design process by methods other than cut-and-try. Multivariable curves, nomograms, and other short-cut techniques have been tried by the hundreds. Some of these are excellent approximations to a design and help the inexperienced designer to select the proper core size or punching dimensions as a start. Few of these are accurate or detailed enough to yield a complete design because of the limits to the number of variables which can be handled by 2-dimensional graph paper.

A third process of design which has been successfully used is the "automatic-convergence" method. This approach is neither cut-and-try nor pure synthesis, but it contains some of the features of both. This process entails the estimation of some of the independent variables and then a step-by-step synthesis of the design, usually one or two variables at a time. As the process proceeds, the design variables are continually improved by convergence techniques until they cease to change. When this occurs the design has been accomplished. The automatic-convergence process is very difficult to describe for any complicated apparatus since it requires that design judgment be built into the process. Once it has been described in an intelligible fashion, however, the design process can be carried out by a clerk rather than an engineer. In fact, an engineer would not wish to use this method of plodding along mechanically since he would immediately spot short cuts in a specific design to speed the process. Yet the automatic-convergence method, as will be seen, has proved itself invaluable in the application of digital computers to design.

EFFECT OF DISCRETENESS OF VARIABLES

In the foregoing it has been tacitly assumed that the design variables could be varied continuously in infinitely small increments by the designer within the predetermined limits. Obviously this is not always the case in practice, because of manufacturing requirements, available tools and dies, industry and company standards, and sometimes common usage (for instance, the use of fractions of an inch). As the modern electrical industry is becoming more standardized and more automated, this discreteness of the design variables becomes more and more important and thus warrants further analysis and discussion. Normally, some variables (for instance, flux density and current density) are continuously variable, others such as wire dimensions are discrete in smaller or larger steps. All combinations of continuous and discrete variables are theoretically possible and, in fact, great variety is found for different apparatus and for different manufacturers. To visualize better the importance of this problem, consider two extreme idealized cases: 1. the completely custom-built product, and 2. the product completely assembled from available standard components. In the first case of the custom-built product, such as a large power transformer, the designer has all the variables at his command without restrictions, except for the fundamental laws of science and certain upper and lower limits of manufacturability. His job to determine the sets of simultaneous values of these variables which, subject to the boundary conditions, will minimize or maximize the dependent variable which has been assumed as the "value criterion," for instance, weight, cost, over-all dimensions, or any combination of these and other variables. If all the design equations were linear, the problem would be akin to linear programming, conceptually simple, although the calculations might be quite involved and laborious.

However, since most design relationships are nonlinear, the problem is much more complicated and it is difficult to visualize without previous experience in the art. One simple method of visualization is the following.[11] The relationship of the dependent variable (say, total weight) versus the independent variables may be represented geometrically as a multidimensional surface in a multidimensional space. Assume, for illustration, that there are only two independent design variables. There will be, then, an ordinary surface, on which the lowest point within the boundaries must be sought. This problem is very similar to that of climbing the highest peak in a mountain range without a map. One easy way is the "method of steepest ascent," that is, to keep climbing always along the steepest possible path. Sooner or later a summit will be reached. This peak represents a local optimum (or suboptimum in the parlance of operations research[12]) but there is no guarantee that it is the highest summit of the range, the optimum *optimorum*. In fact, the highest summit may be much higher than the one reached and it may be far away.

Consider now the second case, wherein the product is to be built as an assembly of available standard components. (Obviously, the major design problem is the choice of the type and number of these components but, for the time being, these will be assumed given.) Now all variables can vary only according to a limited number of discrete steps, and all the combinations of these steps are not possible. The pleasant rolling hills of the surface now become a series of jagged ridges and peaks. The "method of steepest ascent" is of no value, since the climber is faced at every step by vertical walls. In this case the problem is to find the optimum combination of the possible values of the variables, and almost always it will be necessary to sacrifice progress along one variable, to achieve a larger gain along the others. It is also evident that, other things being equal, in this second case the total weight will be generally somewhat greater than in the first case. That is, a reduction in the number of possible steps is usually accompanied by an increase in weight, but not necessarily in cost, a fact to be discussed extensively later.

In practice, the designer must reckon with discreteness of two different orders of magnitude. The first is small-scale and is due to manufacturing requirements. For instance, the available wire sizes may vary according to the standard number series, the width and length of the steel laminations in 1-inch steps, etc. The other is conceptually more important. Due to physical characteristics, shipping limitations, manufacturing capabilities, etc., one type of construction is used below a certain limit, another above this limit. This, for instance, is the case for high-voltage windings in core-type transformers wherein two widely different constructions, continuous-disk and layer-wound, are used respectively below and above a certain BIL (basic impulse insulation level). This BIL is not absolutely fixed, but may vary somewhat, and there is a "grey zone" of overlap.

This phenomenon of discreteness is inherent in the design process, and to ignore it would be an inadmissible simplification of the problem. In fact, with the present trend of the electrical industry towards standardization, mass production, and automation, discreteness is becoming more and more important.

It is also important to note that different knowledges, skills, and types of personality are required of the designers for the two cases just considered. The designer of the custom-built product should be analytically minded and accurate. His job is to use the most refined and accurate methods of analysis so that the specifications may be met without any waste in material. The more accurate he is, the fewer will be the required "safety factors" and the more economical the design. The point of diminishing returns in his work is reached when the time and effort spent in refining a calculation is equal to the cost of the material saved. His skill is similar to that of a mathematician. The designer of the product assembled from standard components requires less analytical but more creative ability (in the artistic sense). His job is essentially to visualize the best opportunities in selecting the components and putting them together. His is a skill similar to that of the architect or the draftsman. Finally, both analytical and creative skills are required for the most difficult job in design: the establishment of the type, number, and characteristics of the standard components.

Impact of Digital Computer

Both analog[13] and digital computers have been used for the design of electric machines. It is safe to say that the digital computer is now far ahead of the analog in the broad design area. This is principally because of: 1. the incapacity of the analog computer to handle the discreteness of the design variables, and 2. the truly explosive progress of the digital computer in the last few years. Harder[14] states that there has been a ten-to-one increase per year in computing power, as measured by the speed, size of fast-access memory, flexibility, and reliability. Also, there is no evidence that this ratio of progress will diminish in the foreseeable future. There has been a parallel, and equally striking, reduction in the time and cost per computation. Harder states that a computation requiring 2 weeks on a desk calculator, and costing $300 only a few years ago, now costs 3 cents on a high-power computer, a reduction of 10,000 to 1. The ratio of reduction in time is even higher, with present commercial computing speeds as high as 40,000 additions per second. It should be noted, however, that these cost figures do not include the programming expense, which may be quite considerable in dollars and man-years.[15]

The characteristics of modern computers, the principles of operation, and the programming techniques are well known[14,16] and will not be repeated here; only the principal characteristics will be listed which make this new and powerful tool extremely well adapted and useful to electrical design: 1. high speed and low cost per calculation; 2. flexibility; 3. large memory, of which a considerable portion has extra-fast access; 4. high input and output speeds; 5. logical ability; 6. high speed in making logical decisions; 7. the possibility of achieving an unlimited number of loops in the program, by using the stored-program and address-modification techniques; 8. extremely high reliability and accuracy; and 9. spectacular and continued improvements in the hardware, as has been mentioned, and in the programming art.

The justification for applying computers to the design of electric machines arises from these characteristics and is threefold: computers, when properly applied, save time and money and, most important, make possible calculations which would be impossible by other means. This last factor, in turn, contributes to technological progress and to additional savings. The outstanding characteristics of the digital computer having been reviewed, the discussion will now turn to its application to electrical design and future developments in this field.

Application of Digital Computers to Design

Design Analysis

In applying the computer to electrical design, the first method naturally coming to the mind of the designer is to use it as a glorified slide rule for performance calculations or design analysis. Considerable advantages over calculations by hand have been obtained by this method, especially when it is possible to introduce in the program more refined and accurate calculations than are used in the hand process. Essentially, in the analysis design method, the designer estimates the design variables and the computer calculates the performance of the apparatus. In most cases the calculated performance will not agree with the specifications, and the designer must modify the initial estimates. This 2-step process is repeated as many times as necessary to meet the specifications within the allowable tolerances. Thus the design loop has a human portion (the modification of the estimates) and a computer portion (the performance calculation), as shown in Fig. 2. This human intervention in the program has two major disadvantages. The first is common to both design by hand and by computer. Since the modification of the estimates depends upon the ability, judgment, and experience of the designer, there is no guarantee that in the successive loops the results of the calculation will come always closer to the specifications, and that the design is gradually improved. In fact, an inexperienced designer might conceivably waste much computing time and never achieve the desired results.

The second disadvantage, to use an electrical metaphor, is due to the mismatch of impedance between the designer and the computer. Medium-sized and large-sized computers presently used in design are between 100 and 10,000 times faster than the human mind. A considerable portion of the expended time is required for data input and output, rather than in performing calculations. Thus the efficiency of the design loop is very much lowered by its weakest link, the designer, and by the necessity of reading the new input and printing out the new output instead of keeping it within the memory. Furthermore, as has been stated, there is a marked trend towards faster and better computers. Yet, the capacity of the human mind will remain more or less the same and thus will become always a greater bottleneck in the design loop. The design method of analysis, however, has certain advantages[8] and may be the best in introducing the computer to a group of engineers, who may initially regard it with suspicion, as a potential threat rather than as a willing and docile helper. This approach also avoids the actual or imagined fear of centralizing all design knowledge within the small computer staff. From a psychological point of view, this may be quite valuable in the initial stage, since the individual design engineer has complete control over the making of decisions in the design process. Thus his prerogatives and responsibilities have not been encroached upon.

The next obvious step is the removal of the human element from the design loop. This requires the development of a new system, conceptually different from the hand system, since now the machine must obtain by itself without human intervention a design which meets all the specifications. Or, if this is not possible, it must point this out in the output. Thus the process is conceptually very simple (Fig. 3, contrasted to Fig. 2). Since all decision making is now entrusted to the machine, it is necessary to develop a foolproof, or almost foolproof, automatic procedure. For a smaller computer, for lack of storage capacity and speed it may not be possible to concentrate all decision making to the machine. One solution is to let the designer make initially the major decisions concerning alternate methods of construction for instance, disk versus layer winding; and to let the computer obtain a design with this type of structure which meets the specifications. Of course, this design may not meet the manufacturing or shipping restrictions, or be the best. Then, the designer must try out a new one. The next step is, of course, to have a complete design synthesis wherein, for valid specifications, the computer will always achieve a design valid from all points of view.

Design Synthesis

A practical method of synthesis is shown in Fig. 4. Although this method was first developed by the authors for the transformer design problem, the principles have been extended to other types of products. It is felt that these ideas are general enough to be applicable to all electric apparatus. Each of the blocks will be described in detail in the following, with particular emphasis on the over-all problem of design synthesis.

gram and describes how the apparatus to be designed must perform. The electrical rating of the apparatus, covering such features as capacity, frequency, number of phases, and terminal voltages, is included along with the desired operating characteristics such as regulation, losses, temperature rises, etc. Limiting physical dimensions determined by shipping requirements or installation problems would also be necessary.

Block 2. Read Performance Specifications and Select Design Data in Accordance with these Specifications: Once performance specifications are known, many items of design data may be determined. For example, in designing most electric apparatus, when the BIL is known the minimum electrical clearances between various points in the apparatus are fixed. The types of components to be used and the data to describe them may depend on whether the apparatus is to be single-phase or 3-phase. Some design practices may change with the capacity of the unit and recognition may be made of this. Since physical size is unknown at this point, any design data which depend on it should be estimated from available information. These data will be revised as the design proceeds and as information concerning physical size becomes available. The amount of information which must be available at this stage in the design process depends largely on the complexity of the apparatus involved and the scope of the computer program. A narrow program applying to one type of construction for a simple apparatus might require very few items of design data. A broad program applying to several types of construction for a complex apparatus could need thousands of items of design data. The computer program to sort through these data and select those items peculiar to the apparatus described in the performance specifications may require more program instructions than a small or medium-sized computer can handle.

Block 3. Estimate Starting Values of Key Parameters: For reasons discussed in this paper, most practical design problems are incapable of direct solution in closed form. If this were possible, one could proceed at this time to calculate values of the design variables to meet the desired performance specifications. Since it is not possible, some provision must be made for estimating initial values of the design variables. These variables may be flux density, current density, core-punching sizes, etc. The authors have found that usually it is not necessary to be very accurate at this point because if the remainder of the program is properly constructed the design will automatically converge to the desired design regardless of the initial values.[2] The difference in machine running time between a very accurate start and a very inaccurate one is only 5 to 10 seconds on the IBM *705* computer, for a preliminary transformer design requiring 1 to 2 minutes in total.

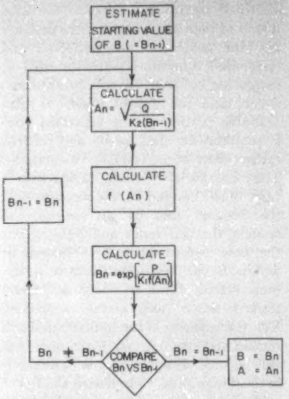

Fig. 5. Block diagram of iterative process

Block 4. Design Apparatus Using Available Design Data and Variables: This is the heart of any synthesized design program. It requires the greatest skill to describe and will probably use the largest number of computer instructions. The form that it takes will depend on the type of apparatus being designed and the degree of design completeness desired. The order of events within this block is quite critical in effecting convergence. The person who constructs this segment of the program must not only be very familiar with the apparatus and the design problems peculiar to it but he must also be extremely creative since little precedent will exist for the necessary manipulations.

During this phase of the design process, new values of the design variables will be generated which will be better than those available at the beginning. The authors have found that iterative techniques are very useful at this stage, particularly when the performance relationships involve nonlinear functions. For example, suppose that the following relationships exist:

$$P = K_1[f(A)] \ln B$$

$$Q = K_2 A^2 B$$

where P and Q are performance characteristics, A and B are design variables, K_1 and K_2 are constants.

With P and Q known, it is desired to find values of A and B to satisfy particular values of K_1 and K_2. An iterative process to obtain the solution is shown in Fig. 5. In this case $B_n - 1$ is equated to B_n but the converging process could be changed to some form of weighted averaging of the two most recent values of B, if this gave quicker results. If the reader can imagine a complex system of many performance equations with a corresponding increase in the number of variables and with dozens of limitations upon the system, he has some picture of the typical design process. The authors have discovered that it is usually possible to describe such a complicated system by a series of relatively simpler systems. These new systems are simpler in that only two or three variables are allowed to vary at one time and the remaining variables are held fixed at that time. The results of this process are carried over to the next system and there are many iterative loops within other iterative loops. The order in which the smaller systems are processed depends on the relationships between variables. As with any iterative procedure, to effect convergence the most sensitive variables must be dealt with first, the next sensitive second, and the least sensitive last. As values of the variables are improved, better information about the physical size of the components becomes known. Any design data which depend on physical size must be continually checked for validity and changed if necessary.

Whenever a question arises as to which is the best way to proceed, for example, which is the best type of component to use, how should the components be arranged, what balance of active materials should be used, the program must contain all the criteria for making the decision. The judgment which has been traditionally exercised by the designer must be built into the computer program so that the machine will always make the same decision as the man, under the same set of circumstances. The subsequent analysis of various design methods and the discarding of all but one which will be used in the computer program is one of the most rewarding aspects of this type of work.

At the completion of stage 4, values of all the design data and variables will be known. There is no guarantee that this is the proper design, however, since several estimates will still be factored into the design. The only way to prove the correctness of the design is to calculate the complete performance and compare this with the desired performance.

Block 5. Calculate Performance of Apparatus: During this stage the computer will perform the design analysis and calculate each of the performance characteristics of the apparatus. Some of these calculations may be simple; others may be mathematically very complex. This is a relatively easy stage to describe by block diagram and to program, because of its straightforwardness and because it ordinarily does not involve judgment.

Block 6. Is the Performance Satisfactory? Each of the calculated performance characteristics must be compared with the desired values to see if it is satisfactory. Criteria for acceptability must be set up. For example, it might be desirable for one characteristic always to be below the desired value. Another characteristic might have to be with ±1% of the desired value. If all the calculated values are within acceptability limits the design can be said to be satisfactory. If one or more of the calculated values are outside of acceptability limits the design is not satisfactory and at least one more iteration of stages 4 and 5 is necessary.

Block 7. Adjust Values of Key Design Variables to Effect Convergence: Because the design is not satisfactory, values of the design variables are not correct and must be improved. Knowledge of the interrelationships between variables is most important for determining how the variables should be changed at this point. Possibly the most recent values developed in stage 4 should be used. This is usually the case except where it induces oscillations between values used to start stage 4 and values available at the completion of stage 4. For this oscillating case a system of weighted averages will usually suffice and the weighting factors may be used to speed up convergence. Rather than spend much time worrying about this problem, the authors have discovered that it is better to complete the remainder of the program and use the program to study the behavior of the design process in order to determine the best solution.

Blocks 8 and 9. Print Design Record: After the design is satisfactory, a complete description of the physical characteristics of the apparatus, along with the calculated performance characteristics, should be printed. Any problems which the machine encountered during the design process should also be printed out for the convenience of the design engineer who will evaluate the design.

One advantage of the synthesis method described is that it allows the apparatus to be designed in whatever detail is desired. If a very rough design is adequate, stages 2 and 4 may be made small and simple. If the program is to be used for generating instructions on how to construct a complex apparatus, stages 2 and 4 could become so large that they would require a large-scale computer. The authors have discovered that there are advantages to thinking of the total design process as having two distinct phases, preliminary design and final design; see Fig. 1. The preliminary-design phase is primarily concerned with the design of the major components of the apparatus and omits any detail which does not significantly affect the weight, physical size, performance, and cost of the apparatus. The final-design phase supplements the preliminary design by generating all the additional detail required to describe the apparatus for manufacture. Some advantages of this concept are:

1. In most product businesses, many designs are required for apparatus which will not be built, for example, to answer customer inquiries and for design studies. A preliminary design is adequate for such purposes.
2. A final design will require more computer programming effort than preliminary design. Also it will not be run as frequently.
3. A final design will take much longer to run on a computer and therefore should not be run unless the detailed information is necessary.

It has been the authors' experience that the preliminary-design phase is the "workhorse" of an engineering organization which designs custom-built apparatus.

Conceptually there is a major break between preparing a program for design analysis and one for design synthesis. This is due to two basic differences. The first is that performance calculations are essentially mathematical with few logical decisions, and are most appropriately done on a computer of the scientific type. Design synthesis on the other hand, as we have seen, entails a tremendous amount of selection and processing of data and logical decisions, which may require more time than the actual performance calculations. A computer of the "business" type is probably best suited for this application. In fact, optimum utilization of the computer memory and speed may be obtained by using a machine with variable word length, such as the IBM *705*. This machine has high speed in reading, writing, and making logical decisions, but relatively slower speeds in making additions, subtractions, multiplications, and divisions, which may amount to only 30% of the total instructions. Usually the 10- or 12-decimal digit word length of scientific computers is excessive for design applications which, as is well known, usually require slide-rule accuracy except for particular subroutines such as reactance calculations.[17] Recognizing this in the early stage of their apppication of the CPC to transformer design, a 5-digit plugboard[18] was developed for the CPC, which in practice doubled its very limited storage capacity and speed. It is indeed significant that two of the largest electrical manufacturers in the U. S. have chosen an IBM *705* (a "business" machine) rather than an IBM *704* (a "scientific" machine) for transformer design synthesis.

The other basic difference between programming design analysis and synthesis is the following. The rules and formulas for performance calculations are readily available from the fundamental laws of electricity, textbooks, standard practice, and test results. These may be simple or complex but they are available. In contrast, the rules for making decisions in design synthesis, for selecting components, for modifying the initial estimates, etc., are usually not written down, but are hidden in the mind of the designer. In many cases these decisions will differ according to the ability, experience, training, and personality of the designer and it may be difficult to reconcile the various experts and "pin them down" to a unique set of rules. In the hand method this may not be a serious drawback and it permits the injection of the designer's individual characteristic into the product. As long as no clean-cut perference can be established for the choice of one alternative, it may be wise to avoid making a premature decision. With the advent of the computer, this avoidance of decision making must come to an end. It is necessary therefore to write down and describe to the most minute detail all these unwritten rules and practices, and choose one, and only one, of the possible alternatives. This may require tact, perseverance, and time in a group of engineers who have worked for many years, as described previously. In making these choices, it is only natural that the criterion is the "best" alternative in every case. This leads directly to the subject of optimization, to be discussed later. For the time being, note that there may be many different opinions as to what is the best alternative, and that in many cases there is simply not enough knowledge available for making a decision. Yet a decision must be made in order to write the program. It may be felt that this is a serious drawback, from an economic standpoint, since possible better alternatives will not be considered, and from a psychological one, since the individual designer may feel that he cannot use fully his judgment and experience. In some cases, many of the possible savings may be lost, if the designer modifies the computer-produced design by hand, to improve it according to his judgment or avoid using alternatives which he does not like.

Fully realizing these factors, and their incapacity of being absolutely sure of having the best alternative in the computer, the authors in their *705* programs for transformer design have adopted the policy that the designer may always override the program in many important fields. The program works this way: if only the specifications are furnished to the computer, it will produce a design according to the program, which embodies the "best" alternatives, as obtained from the best available judgment and experience in the design groups. By adding additional input, the designer may specifically override the computer program and obtain alternative designs, which he may compare, if he wishes, with the routine design. This flexibility is extremely valuable in studying new ideas, proposed new developments, or special customer requirements. It maintains an always "alive" design program and keeps the individual designers happy.

It is seen that, the design synthesis method leads, sooner or later, to an inescapable consideration: design optimization. This is a fascinating subject and herein still lies the tremendous future potentialities of this powerful new tool, the digital computer which, in the authors' opinion, has been used to only a minor degree of sophistication.

DESIGN OPTIMIZATION

Design optimization is the ultimate aim of every designer. It is the authors' conviction that true optimization will be possible only through the modern, high-speed digital computer. In considering the broad problem, one is faced immediately with that bugaboo of operations research: suboptimization. Why this is so is obvious: one person cannot optimize one variable and the next person optimize the others. This would happen in the example, given earlier, of the surface of hills and peaks, by selecting a fixed value of one variable and climbing to the highest point of that cross section. There is no guarantee that it is the highest summit, or even a secondary one. Thus, optimization is a complex subject for various reasons. First of all, at least theoretically, it cannot be accomplished by separation of the variables: it is an all-or-nothing process. Second, a "theory of value" must be establihsed; that is, a decision as to what to optimize. In many cases, including design, more time, money, and effort are wasted in trying to optimize the wrong variable, than in entirely omitting optimization. The "value" may be weight, dimensions, cost, quality, customer satisfaction; the balanced best interest of the manufacturer, the customer, and the public; or a combination of these quantities, which are progressively more difficult to define and determine mathematically. The point is reached where it is impossible to write a computer program for such elusive criteria. The over-all decision is best left to the judgment and experience of the manager who is responsible. This, of course, is the general approach of operations research which furnishes the pertinent data to the executive and allows him to make the final decision. Furthermore, optimization is strictly a relative criterion. A given design is only optimum subject to the imposed boundary conditions and to the criterion chosen as "value." Thus the design with minimum weight is seldom the design of minimum cost to the manufacturer. In turn, the design with minimum cost to the manufacturer is not always the design with minimum capitalized cost to the user, and the optimum design taking into account both the cost of the manufacturer and the user may not be optimum from the standpoint of the over-all economy, etc. Here again is the bugaboo of suboptimization.

To see how optimization is complicated and laborious, even for a large computer, consider the idealized case, described in the foregoing, of a product made exclusively of standard components. Assume that the product must meet the following three characteristics specified by the customer: 1. reactance, 2. current, and 3. system voltage. Assume that the reactance values must be met within ±1% and the current values within ±2.5%. The range of rating usually requested by the customers varies from 1 to 200 in reactance and from 1 to 36 in current, and there are nine standard values of system voltages. It is easy to see that the total number of designs to be made would be

$$\frac{\ln 200}{\ln 1.02}\times\frac{\ln 36}{\ln 1.05}\times 9=270\times 75\times 9$$
$$=185{,}000 \text{ designs}$$

At present, it is not known a priori how to optimize a design. Since there are seven independent design variables in all, many different combinations of these variables, say, 10 or 12 should be tried for each design by the synthesis method. Even after performing about 2 million designs, which may require 30 seconds each on a large computer (costing $500,000 per year), i.e., about 8 computer-years at 40 hours a week, or 4 million dollars, it is still uncertain as to whether the optimum has been achieved. Obviously the answer is to perform each design as it is required, and to try as many different variations as long as there is computer time available and as long as the expected amount to be saved is equal to the cost of making an additional design on the computer.

Another way to look at this problem is, so to speak, to turn it upside down. As has been mentioned, there are seven independent design variables. For each one are known the minimum and maximum values and the number of finite intermediate values. For instance, the value of one design variable usually varies between 4 and 20 and must be even, so that there are only nine possible values in all. Assume that there are ten possible values, on the average, of each design variable. Thus 10^7 or 10 million combinations in all must be tried. However, these are strictly performance calculations on the computer and since they are done according to a mass-production technique they require only one hundredth of the time of an individual design by the synthesis method, or 0.3 second each. Thus the total time required would be about 800 hours or about $200,000, which is not an unreasonable figure for this amount of work. Now that all possible combinations of the design variables are available, it is certain that they contain all 185,000 combinations of the customer specifications mentioned, if these specifications can be met at all with the available components. The next step is simply data processing and may even be done on conventional punched-card equipment. The 10 million designs are sorted in 185,000 packs, each corresponding to one set of customer specifications. Each pack, which contains, on the average, 54 alternatives, is sorted according to the computed cost, if this is the chosen criterion. The 53 more expensive designs are discarded and the optimum is retained. Now, it is absolutely certain that the optimum has been obtained, i.e., the optimum for the boundary conditions chosen. But the choice of the number of these variables may be questioned, for instance, the number of standard wire sizes, and so on, ad infinitum. This example, which was actually tried out by one of the authors, shows conclusively that: 1. optimization is a relative concept and, most important, 2. it will become possible only through the largest and fastest computers now available or planned.

In the practical realization of their transformer design program, which is very much more complicated than the program just described, the authors chose a realistic and down-to-earth approach towards optimization, and determined on the following procedure: 1. to try to achieve the optimum within the present status of knowledge of design; 2. to strive continuously to improve the optimum by developing new knowledge and to use the computer extensively for this; and 3. to utilize the store of experience in the mind of the individual designer by making it possible to override the computer program, as discussed in the foregoing.

Using manual design techniques, the designer is seldom able to investigate many alternative constructions to determine the best. Therefore it is extremely important for him to develop rules of thumb to guide him toward on optimum design. The authors have found that these same or similar rules, when built into a computer program, greatly aid the computer to reach an optimum design. Several examples taken from the transformer design problem will help to illustrate this.

Through the years, studies have been made on the optimum "form" of a transformer. Since the designer has almost complete control of whether a given transformer will be short and squat or tall and slim, this is extremely important. Based on existing rules of thumb a relationship between optimum transformer height and kva was derived and built into the program. Essentially, it stated that transformer height should increase with kva up to a maximum allowable shipping height. Above this point, maximum possible height gives an optimum form. The selection of the most economical type of winding to use for a particular design has traditionally depended on the axial turns per inch of core window and the total cross section of conductor desired. To verify these relationships, an extensive study was made on the CPC wherein several types of windings were designed to accomplish the same objectives. By relating costs back to some of the design variables, it was possible to set up rules concerning the selection of winding types and to build these rules into the computer program. Also, since it can be shown that optimum copper utilization is reached when the winding temperature rises of each of the windings are equated, this rule is built into the computer program. The combination of these and several other rules results in a design very close to optimum.

STANDARDIZATION

Consider again the first idealized case discussed previously, the custom-designed and custom-built product, with practically no repetition of ratings over the years. It has been seen that the point of diminishing returns on refining the calculations is met when the cost of such additional calculations becomes equal to the expected savings in material. Since the digital computer reduces drastically the cost of calculations, it would appear that considerable savings would be obtained by carrying all designs to the maximum detail and variability, eliminating any discreteness in the design variables. However, this concept is true only for the ideal case and it neglects manufacturability. In practice, electric machines are all more or less standardized and the practical application of the foregoing concept to its ultimate would represent a typical example of suboptimization and would run directly against one of the most marked and beneficial trends of the electrical manufacturing industry: standardization. This leads to a discussion of standardization and this can be done advantageously only by keeping in mind the optimization concept discussed in the previous section.

Standardization, both industry-wide and within a company, department, or plant, has been and is one of the most powerful tools in improving quality, keeping down the total cost and extending the benefits of mass production to wider and wider markets. Basically, its purposes are: 1. to reduce the total cost to the national economy of a given product line, and 2. to make possible increased production per office and factory worker. If it is considered that the requirements of the electrical industry double every 10 years, and that the available workers will increase only a few per cent in the same period in this country, the importance of the second factor may be visualized. Furthermore, no automation can exist without standardization, which in electrical design can take several forms: standard ratings, standard outside dimensions, standard sizes and shapes of major components, standard dimensions of minor components, and standard steps in one or more dimensions of otherwise variable components. These will be designated henceforth as "discrete parameters." The following discussion will be sufficiently general to encompass all these cases.

Here the goal of standardization will be assumed to be the minimization of the manufacturing cost of the product for a given series of specifications and industry or company standards. It is obvious that in the general case variability is required in the design variables in order to: 1. meet the variabilities of the customer specifications and other market requirements, 2. economize material, and 3. fit together the various pieces of the "jigsaw puzzle" as represented by the standard components. The selection of the type and number of discrete parameters is primarily a matter of optimization and, as has been seen, this is not a well-defined area. As has also been seen, the problem is compounded by the fact that all these discrete parameters are interrelated by complex nonlinear relationships, so that the design of one may have a major effect on several others. Thus, the separate optimization of each component does not guarantee an optimized product, and consequently all discrete parameters should be designed together within the framework of an integrated system. It is felt, however, that some general concepts may be developed as an aid in the solution of this problem.

In trying to minimize the total cost, all its major portions must be considered separately; material; drafting expense; engineering expense; manufacturing and clerical expense; and computer costs. It must also be realized that the problem is often seen differently by the design engineer, the design draftsman, and the manufacturing engineer, since each group may overemphasize the importance of the contributions of the items with which he is most familiar.

The design engineer is interested in maximum flexibility and in the best utilization of material which will meet the customer's specifications. As has been seen, this is obtained by having available a very large number of discrete parameters and the effect of the computer is to shift the minimum cost point toward an even higher number of these parameters, since it allows more refined and accurate calculations. Fig. 6(A) shows qualitatively the basic relationship between material cost and degree of standardization, which is inversely proportional to the number of discrete parameters, i.e., the greater the degree of standardization, the fewer the number of discrete parameters.

The drafting and engineering expenses

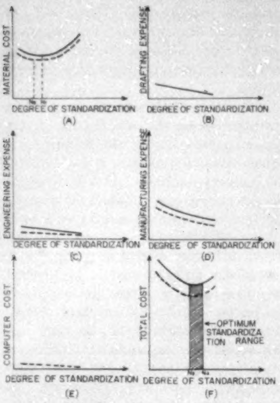

Fig. 6. Theoretical effect of degree of standardization on cost in dollars

— by hand
- - by computer

are basically proportional to the number of discrete parameters, but the slope of the drafting cost curve, Fig. 6(B), is steeper than the engineering cost curve; see Fig. 6(C). In fact, as the number of components, arrangements and discrete dimensions is increased, more layouts and detail drawings are required and more man-hours of creative effort will be expended in engineering and drafting. The effect of the computer on engineering expense is to reduce the slope of the curve, as shown in Fig. 6(C).

Manufacturing expense in general decreases with the increasing degree of standardization; see Fig. 6(D). It has also been claimed that a reduction of this expense will be obtained through computers. Finally, in applying the computer, the following must be considered: the cost of programming, preparation of data in a form suitable for computer processing (punched cards, magnetic tape, etc.), and capitalized running costs. This cost varies linearly with the number of discrete parameters, Fig. 6(E), but the slope is quite small, since the devising of a general program, suitable for a variable number of components is the overwhelming portion of the cost and because, in large machines, the running costs are hardly affected by the increased number of discrete parameters available on tape. Furthermore, if the discrete steps are properly chosen, they can be represented by algebraic equations, and the total computer costs become independent of the number of possible steps in the design variables.

The optimum degree of standardization is obtained when total costs are minimized. To do this, all five cost components of Fig. 6(A) through (E) must be added together, and each contribution weighed by an appropriate factor. The relative value of these factors will depend, just as the shape of each curve, on the particular product and manufacturer considered. For purposes of illustration, assume that material amounts to 40%, manufacturing expense to 40%, engineering, drafting (and computer, if any), expense to 20% of the total cost, assumed to be equal to 100%. Obviously the total cost after introduction of the computer will be lower than before, if the application is worth it, but the same relative proportions may be assumed. Then, the curves of total cost versus the number of discrete parameters will take the general shape of Fig. 6(F) with minimums corresponding to about the same value N_3 of discrete parameters, much less than N_1 and N_2 of Fig. 6(A). It is also noted that the curve of Fig. 6(F) is quite flat around the minimum, as in most similar economic studies, and that therefore there is a certain latitude in the choice of the optimum number of discrete parameters.

This is indeed fortunate, because so far it has been assumed that the problem is static rather than dynamic. As mentioned previously, electric power is doubling every 10 years with correspondingly increased production, and there is a definite rapid trend towards factory automation. This will increase the slope of the manufacturing expense curve and will thus shift the optimum number N_3 more and more toward the right. Since the installation and full utilization of a large computer and any standardization program involves several years of planning and preparation, the selection of the optimum value must be based on the foreseeable future rather than on "present" data, which are essentially past history. Thus, it appears logical to choose the optimum number of discrete parameters in the standardization range N_3 to N_4, as indicated in Fig. 6(F). In this manner will be avoided both the danger of overconservatism, which will lead to the maintenance of outdated custom-built products in this age of mass production and automation, and the excessive enthusiasm of overshooting the mark and "standardizing for standardization's sake" without considering the whole economic picture within the actual requirements of the market.

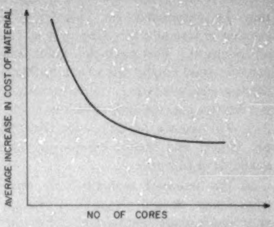

Fig. 7. Effect of number of core sizes on material cost

As an example, these standardization principles were used to analyze the optimum number of core sizes required in the power transformer business. Traditionally it had been felt that it was desirable to have a very large number of core sizes, since this allowed the designer to minimize the amount of active material, magnetic steel and copper, going into the transformer. The relationship between material costs and number of core sizes is shown in Fig. 7. Since most of the internal components of a transformer depend on the physical size of the core, a large number of core sizes results in more drawings, more factory paper, and higher manufacturing costs. An analysis of all factors indicates that it is theoretically possible to reduce the number of core sizes considerably. This requires more material in the product, but nonetheless reduces its total cost.

Finally, the computer, standardization, and automation all contribute to a splitting of the products marketed into two classes: the "standards" which may be designed on the computer and built from a majority of standard components, and the "specials" which must still be designed, for the major part, by the traditional hand methods and built in a job shop. As time passes, the split between these categories and the differences in cost are becoming more and more marked. This is bound to feed back and reflect itself on the market, for instance in price differentials, shorter deliveries, improved service and maintenance, etc. These advantages to the customer will create a larger demand for the standard product, compared to the special. The increased production in the standard area will sharpen more and more the advantages of the standards by allowing increased automation. Thus market and production will influence each other in a beneficial circle steadily progressing towards increased standardization and a better product.

Evaluation

A digital computer represents both high investment and a considerable annual expense. The investment is measured by the man-years required to prepare the design programs and by the cost of the physical installation. The yearly expense is measured by the rental costs, salaries of operating personnel, supplies, and overhead. For one shift, typical annual expenses may be of the order of $100,000 for a medium-sized computer and $600,000 for a large-sized computer. The initial investment may be of the same order of magnitude or larger.

Therefore it is very important to evaluate the contribution of a digital computer to design, and decide whether these high costs are economically justified. Evaluation of the contribution of the computer cannot be restricted exclusively to dollars and cents. This is only one aspect, albeit a very important one, of the entire picture. It appears that a particular computer application to design of electric apparatus' may be justified for one or more of the following reasons.

First, the computer saves money. The most obvious justification is that the cost in dollars to do the job by hand is so much greater than the cost of exactly the same job by computer, as in the classic data-processing application of payroll. This however, is only part of the picture for engineering applications, in that the computer design methods are usually superior to the hand methods, and therefore not directly comparable. In fact, engineers tend to use the computer not to repeat narrowly and unimaginatively what is being done by hand, but rather to obtain the best possible design, with regard to quality, accuracy, speed, and total cost. Actually, as has been shown, the savings obtainable through design optimization are considerably greater than the savings obtained through the reduction of the cost per operation.

Second, the computer saves time. A job requiring weeks by hand may be done in hours or minutes on the computer. This may be very important in giving faster service to the customer, and it is a real asset with respect to competition. Ultimately, it contributes to increased customer good will, better service to the public, higher prestige for the company, and a greater share of the market.

Third, the computer improves the quality of the product because it is usually more accurate than hand processing, and because errors are practically eliminated, once the program has been thoroughly checked out. It may be assumed that the quality of designs being produced by hand varies according to a Gaussian distribution. The effects of the computer are: 1. to raise the mean, since the programs embody the knowledge and ability of the most able and experienced designers rather than that of the average designer; 2. to eliminate almost completely the low-quality tail of the distribution curve for the reasons already stated; and 3. in some cases, to shorten a little the high-quality tail, since able individual designers may create original solutions best suited to a particularly complex job, whereas only the general solution is applied by the computer to these unusual cases.

Fourth, the computer allows the doing of things which cannot be done without it. This is probably the most important contribution and also perhaps the most difficult to grasp in its ultimate consequences. Engineers well know that there are problems, some extremely important, which simply cannot be solved by hand. A typical example is the optimization problem of a product assembled from standard components, mentioned earlier. It requires the computation, analysis, and evaluation of millions of alternate designs, an absolutely impossible task by hand.

Fifth, the computer frees the design engineer from daily routine calculations to truly creative effort, which may be devoted to the improvement of the product and to better service to the customer. It also alleviates the effect of the present shortage of engineers and technical personnel. By making design work less routine and more interesting, more students will be attracted to this field.

Conclusions

The application of digital computers to the design of electric apparatus is at present an accomplished fact. While this application is still young, it has achieved to date important results, technically and economically. The results to be achieved in the future appear even more important, particularly in the fields of design optimization and standardization. The present and future benefits of applying digital computers to the design of electric apparatus may be summarized in terms of lower costs, improved quality, faster and better service, more interesting and rewarding jobs, increased productivity, and more creative effort on the part of the engineering personnel.

Discussion

H. R. J. Grosch (International Business Machines Corporation, New York, N. Y.): The authors made a rather surprising choice when they adopted the IBM *705* for design synthesis. The variable word length feature which is so valuable in accounting work, where data fields may range from two or three characters to hundreds, is not utilized very effectively in technical work, nor is the manipulation of alphabetic information. The much greater arithmetic speeds of the "scientific" machines, and the availability of very much larger random-access memories for even more sophisticated design syntheses which the authors will undoubtedly attempt in the near future, point to something like the new IBM *709*.

In my experience, 30% is an unusually large fraction of instructions to be arithmetic as distinguished from logical. Only a very few programs, notably those like nuclear reactor designs and flutter calculations which involve large matrices, would require a higher proportion. In business applications which involve much rearrangement of data or maintenance of large tape files, arithmetic instructions may constitute only 2% or 3% of the programs.

The General Electric Company's success at Pittsfield and at Hanford in using *705*-type equipment for technical calculations, and Lockheed's success in using *704*-type equipment for business data processing (production control), point up emphatically the flexibility of the big digital computer. Almost any machine can contribute powerfully to almost any class of large-scale data handling. The key is, as always, able personnel and imaginative leadership.

C. G. Veinott (Reliance Electric and Engineering Company, Cleveland, Ohio): This paper was most interesting to me. The authors seem to have started about the same time that I did in putting a digital computer to work on electric machinery design. In the summer of 1953, I was responsible for having had an induction-motor design procedure programmed on a CPC.[1] Later, we followed this by programming a d-c design calculation on the CPC, also d-c armature heating calculations. This experience led us to the decision to acquire a digital computer for our own use. At that time, it was clear that the CPC was already outmoded and we turned to a stored-program computer, the Alwac III. Why we chose this particular computer and how we were then using it for induction machinery design calculations were reported in reference 6 of the paper.

The paper is an excellent discussion of the problems that face one who attempts to apply the digital computer to the practical design of electric machinery. These problems are quite distinct and different from many of the sophisticated techniques used and reported in the mathematical journals. One reason, as the authors point out, is that so many variables are discrete that many optimization techniques are not applicable.

As reported (reference 6 of the paper), we used the design-analysis method first. The first calculation procedure that we programmed on the CPC was that which was then being used by hand, and which required approximately 2 to 3 hours for an engineer or technician. In preparation for a stored-program computer, we developed new procedures and formulas to get a more accurate and more universal method. Some 10 to 12 man-months were expended in the development of the new calculation procedure. Calculations by this procedure required some 8 to 10 hours to perform by hand. This procedure was first programmed on a Datatron, then some refinements were added and it was later programmed on our Alwac. This emphasizes the point made by the authors that with a digital computer it is practical to use more elaborate and more accurate calculating formulas. However, unlike the authors, we did not find these formulas readily available from textbooks.

We used the design analysis method for starting for at least three reasons:

1. If permitted a mass tryout of our new calculating method.

2. It introduced engineers to the computer through a familiar path.

3. It enlisted several engineers in the task of a large-scale tryout of the method over a wide range in machines, so that a far better correlation between test data and calculated data was obtained than would otherwise have been possible.

Some idea of the size of this program may be of interest here. The first program we used (described in reference 6 of the paper) contained 2,900 instructions, 290 program constants, and 360 items of data. After we had made these calculations on some 1,500 to 2,000 motor designs and had studied the results, we developed a newer and better procedure, which also included double-cage induction motors; we then rewrote the procedure entirely from scratch. The new procedure contained some 3,500 instructions, 350 program constants, and 270 items of data. These figures show why we would not have considered an IBM *650* computer adequate for this problem. It could have been done, of course, with the *650* by breaking the program up into parts and working with it in sections as is sometimes done for this type of problem. It is more convenient, however, to have the entire program on the drum.

We have done considerable work in different areas and our findings thoroughly support the conclusions of the authors that the use of synthesis is more desirable and more effective in a large-scale computer. In the synthesis procedure, we also recognize the need for flexibility. The authors refer to this as giving the engineer an opportunity to override the computer program. We would be interested in information as to how this is accomplished. One way is to duplicate some of the outputs on the input form. For example, in designing an induction motor, sometimes the engineer does not care whether the winding is connected in star or in delta; at other times he insists that it be connected one or the other way. We provide a space on the input blank for him to mark or leave blank. If he leaves the space blank, the machine operator types in a zero; the computer "looks at" the zero and then finds the better connection; if the engineer marks down one connection, then the computer will try only windings connected as instructed by the engineer.

To summarize briefly, our computer helps us to produce better and more economical designs of motors, faster. It gives us more output from the same number of engineers. Also, we find that, through the computer, beginners become productive sooner than without it.

REFERENCE

1. *Discussion* by **C. G. Veinott** of DIGITAL COMPUTERS AS AN AID IN ELECTRIC-MACHINE DESIGN, **R. M. Saunders.** *AIEE Transactions*, vol. 73, pt. I, May 1954, pp. 191–92.

Ned Chapin (Stanford Research Institute, Stanford, Calif.): As a statement of the authors' methods, I found the paper valuable and interesting. But I could not find a definite, concise statement of the "philosophy" in the title, unless the authors wish us to consider that a method constitutes a philosophy. It seems to me that it generally does not. May we have a paragraph clarifying the title of the paper?

Consider the following. Three design processes are listed: 1. "...cut-and-try." 2. "... to synthesize the design process," and 3. "automatic convergence." Ignoring the fact that these three are nonparallel in both their logic and their statement, the authors indicate that "design synthesis" (which apparently, although they do not so state, is the same as point 2 just cited) is what they have attempted on the automatic computer. However, the discussion of the method used appears to be what was previously referred to as "automatic convergence." And when the authors take up what they say they feel to be the major area of potential in the use of computers in design work (optimization) their illustration is taken from "cut-and-try." Would the authors clarify the philosophy mentioned in the title of the paper in relation to the implication in point four in the section "Evaluation"? Here, rather than the analytical approach, the authors appear to call for the use of a computer to tackle by "brute force" procedures too burdensome to accomplish by hand. If this is the intention, how do the authors relate it to their more general implication of identity of method and philosophy?

In the discussion of standardization, the authors do not specifically state what they wish to optimize. Yet the discussion of costs appears tacitly to assume that the measurable total cost to their company is to be optimized. Is this the intention?

I feel that the discussion of the effect of the degree of standardization on various types of costs is one of the most valuable parts of the paper, and I hope that the topic will be amplified in a future paper.

Harry N. Cantrell (General Electric Company, Schenectady, N. Y.): The authors are to be congratulated on their successful treatment of a difficult abstract subject. A careful study of the concepts discussed has been very rewarding.

This is a philosophy of the mechanization of engineering design work and as such is important to all interested engineers. It is not restricted to electric apparatus or even to electrical engineering but it does imply a design process that is repeated often enough to be worth mechanizing.

That it is possible and often desirable to mechanize engineering design work does not mean that engineers are obsolete. It does mean that the emphasis in engineering work is swinging toward more consideration of how to design a product and away from the actual design work itself. It also does not mean that engineering work is getting any easier. As the paper suggests, the problems involved in the application of digital computers to design are formidable engineering problems indeed. Furthermore, their solution requires the same thorough knowledge of the design process, the engineering fundamentals involved, and the relationships between parameters that characterize the experienced design engineer. This writer is convinced that only a good, experienced design engineer can define a mechanizable process for designing a product. This means that the engineer must learn a great deal about computers and more about mathematics and numerical analysis, but experience has shown that most good engineers have no great trouble in becoming proficient in these subjects.

Mechanizing engineering design also raises interesting management problems on such subjects as design responsibility, training of new engineers, and engineering organization, but these are beyond the scope of this discussion.

This writer has found the distinction between design analysis, design synthesis, and design optimization, as given in the paper, to be very helpful. These are really three very different stages of mechanization in which each stage is often several times more difficult to achieve than the preceding one.

D. J. Herder (General Electric Company, Lynn, Mass.): It is worthy of note that the authors have had the courage to tackle the problem of including manufacturing costs. While the inclusion of these costs is usually more difficult than the engineering problems involved, it is only by this means that the designer can utilize fully the capabilities of the high-speed digital computer for design optimization. The authors are to be especially complimented for this forward step. It would be interesting to have further details of their approach to the cost problem.

The authors break down design work into preliminary and final design. In either case the computer is used each time a design is required. In the case of preliminary design or advance design, the computer program may be used in another way which is sometimes overlooked: For advance design work, especially in determining the effect of new materials or new technological developments, quick, reasonably accurate hand methods are still of value to the designer. The decided advantage is that the logic is not buried in a maze of computer instructions. The computer can be an invaluable aid in this. Using design analysis programs, thousands of calculations may be made on the computer with many levels of the variables. The results may be properly plotted in such a way as to revolutionize the hand calculation methods for use in design synthesis procedures. While I agree that 2-dimensional graph paper has its limitations, it is still a valuable aid in visualizing the effects of variables. Only through such visualization can the designer's talents be fully developed and utilized.

As an example, in rotating machinery design, after the computer is used to grind out page after page of answers, it is possible to plot sets of curves of temperature rise versus ampere-turn loading for various rotor diameters, insulation thicknesses, and hydrogen pressures. With these curves the designer may choose his allowable temperature rise, enter the curves for the proper insulation thickness and hydrogen pressure, and read off the approximate rotor diameter required for any desired number of ampere-turns. Without the computer these curves would never exist because the time to prepare them by hand calculation would be prohibitive.

By repeated use of this approach, preliminary design synthesis can approach a series of reasonably straightforward steps which can be taken by the designer at his desk in a shorter period than is required to fill out input form sheets and to wait for the results from the computer, especially if the computer is used under a closed-shop arrangement.

P. A. Abetti and S. B. Williams: The authors wish to thank the discussers for their interest. We feel that the discussions, which are based on considerable knowledge and experience, add to the understanding of this relatively new and complex subject.

The question of which type of computer is best for design synthesis is a difficult one, and the answer depends largely on the degree of synthesis desired and the amount of detailed information to be generated. The authors spent several months studying this problem before the order was placed for an IBM *705*. While design synthesis is a more technical problem than payroll, the most difficult area of programming is not the calculation of performance, but rather the selection of the proper design data and the duplication of the decision-making process of the design engineer. Design synthesis of complex apparatus such as power transformers involves much rearrangement of data and maintenance of large tape files. The data fields in these files may vary from two or three characters to hundreds. The numbers used for calculations are rarely over four digits long. Confirming Dr. Grosch's observation, arithmetic instructions in many sections of our programs amount to considerably less than 30% of the total instructions. The manipulation of alphabetic information is a necessity if the machine is to communicate with humans. There is presently no computer commercially available that is ideally suited for comprehensive design synthesis work. Writing the specifications for such a machine would be difficult. In our opinion, the ideal computer would have very large random access memory, variable word length, externally fixed point and internally floating point arithmetic, a simple command structure, and would cost about one-tenth of its current price. After one year of operation, we still believe that the IBM *705* is the best available large computer for our particular problems. Rapidly changing computer technology may soon alter this picture.

Mr. Veinott's discussion of how he allows the design engineer to override the computer agrees exactly with the method which the authors and their colleagues have used. Before making a design choice the computer is told to "look at" a certain input position. If that position is blank, the computer chooses the proper data in what it considers to be the optimum fashion. If the input position is not blank, the machine uses the data found at that position. This feature is extremely useful for design studies of alternate constructions. Since it gives the engineer some control over the design, it also helps to allay the suspicion that the computer has taken over design responsibility.

The pitfalls that may appear when engineers try to discuss philosophies are very well pointed out by Mr. Chapin's discussion. We did not intend to imply that method and philosophy are the same. Rather, we meant to say that not only the methods by which we design apparatus are undergoing radical changes because of computers, but also that the broader aspects of the purpose of design and of the principles of design are changing. With a computerized design procedure available, we can afford to make many more designs and for the first time study the problems of optimization and standardization. The design engineer becomes an evaluator rather than a slide-rule pusher. Actually, the impact of computers is even more basic. Since the "brute force" approach of applying existing design systems to a computer is not economical, a complete change in the manner of codifying and tabulating design data may be necessary. The way in which design information flows through an engineering organization may be altered. Computers force simplification, systemization, and standardization of engineering design data and procedures.

Generally, the three design processes of analysis, synthesis and optimization are at different stages of sophistication, as Mr. Cantrell points out. To select one of these as most suitable is analogous to choosing among creeping, walking, and running. Without having gone through the first stage, it would be very difficult to tackle the second. Without having solved the second, the third would be impossible.

In the discussion of standardization, the authors intended to optimize the total cost of the product which benefits both manufacturer and user, while meeting all of the user's requirements and applicable standards.

In conclusion, we should like to summarize our philosophy of applying digital computers to the design of electric apparatus. The digital computer should not be used as a glorified slide-rule, to repeat without imagination what is being done by conventional methods. Rather it should be used according to more and more sophisticated methods, to do things which could not be done previously, such as complete design optimization and optimum standardization. Only in this manner will it be possible to take full advantage of this powerful new tool and to utilize completely the creative abilities of the design engineer.

Applications of Nonlinear Magnetics

HERBERT F. STORM
MEMBER AIEE

Synopsis: Quite deservedly, magnetic amplifiers have been given very wide publicity.[1-10] While much attention has been focused on the saturable reactor as a vital part, if not the only part, of a magnetic amplifier, the usefulness of the saturable reactor for other functions than amplification is not as widely appreciated.

It is the object of this paper to show that the very same saturable reactor, or, to put it more broadly, the very same saturable-core device, which is the heart of the magnetic amplifier, will produce important effects besides amplification. Such effects find utilization in counters, timers, voltage and current references, frequency multipliers, firing circuits for thyratrons and ignitrons, pulse-shaping circuits for magnetrons, rectifying circuits without conventional rectifiers, bistable flip-flops, frequency detectors, square-wave oscillators, and many others.

The method of presentation is first to consider the saturable-core device alone, and then in combination with other circuit elements such as resistors, linear inductors, or transistors. To facilitate absorption of the subject matter, only one component at a time will be introduced. The vast area of nonlinear magnetic devices, however, cannot be covered here completely. Therefore, the saturable-core device and other circuit components will be discussed only in combinations without repetitions; i.e., the circuits described contain only one representative of each type of circuit element. It will be seen that this method permits discussion of the fundamentals of most nonlinear magnetic devices with an irreducible minimum of components. Many references for further study will be found at the end of the paper.

IN ITS SIMPLEST FORM the saturable-core device consists of a ferromagnetic core with a single flux path, and one or several windings which are linked with essentially the same flux path (Fig. 1). This device will be designated by the abbreviation *SR* and no differentiation will be made between a saturable reactor, a saturating reactor, or a saturating transformer.

For didactic purposes, a toroidal core covered entirely by each winding is the preferred form. The ratio of outside to inside diameters of the core should not exceed 1.4. A suitable core material is anisotropic 50-50 nickel-iron, such as Orthonol or Deltamax.

The dots in Fig. 1 signify winding polarities. The voltage across each winding is defined as positive when the terminal with the dot is more positive than the other terminal. A current is called positive when it flows in the direction of the polarity arrow. The magnetomotive force is called positive when derived from a positive current.

Nomenclature

AT_c = coercive ampere-turns
E = supply voltage, volts, avg (average)*
E_G = gate voltage, volts, avg*
E_L = voltage on inductor L, volts, rms*
E_O = output voltage, volts, avg
E_m = maximum value of voltage, volts
E_C = capacitor voltage, volts, rms
E_R = voltage across resistor R, volts, avg*
$E_{G,C}$ = combined voltage across *SR* and C, volts, rms
e = supply voltage, volts, instantaneous
e_G = gate voltage, volts, instantaneous
e_O = output voltage, volts, instantaneous
e_L = voltage on inductor L, volts, instantaneous
e_R = voltage on resistor R, volts, instantaneous
f = supply frequency, cps (cycles per second)
I = load current, amps (amperes), rms
I_C = capacitor current, amps, rms
I_G = gate current, amps, rms
i = current, amps, instantaneous
N = number of turns
R_G = resistance of gate, ohms
R_L = resistance of load resistance, ohms
SR = saturable reactor, saturating reactor, saturable transformer
T = period of 1 cycle, sec (second)
t = time, sec
t_s = time of occurrence of saturation, sec
Φ_s = saturation flux, maxwells
$\Delta\Phi$ = flux change, maxwells
ϕ = flux, maxwells, instantaneous

SR Alone

Counter

Counting can be accomplished by utilizing the memory properties of a magnetic core. One form of a counting device, Fig. 2(A), consists of an *SR* which will energize the load after having received a predetermined number of pulses. The supply voltage e consists of pulses of constant volt-seconds, Fig. 2(B), whose number represents the number to be counted. The core properties are shown in Fig. 2(D). Before the count starts, the core has been reset to negative residual flux, as indicated by point O in Fig. 2(D). The first voltage (counting) pulse increases the core flux to a level indicated by 1 in Fig. 2(D), and the flux will remain at this level until the next voltage pulse arrives. As long as the core is unsaturated, the supply voltage appears almost exclusively across the terminals of the *SR*. This may be expressed as $e_G \approx e$. The flux $\Delta\Phi$ follows from

$$e_G = \frac{N}{10^8}\frac{d\phi}{dt} \tag{1}$$

$$\Delta\Phi \approx \frac{10^8}{N}\int e\,dt \tag{2}$$

During the presence of the voltage the load is traversed by a small magnetizing current, Fig. 2(C), determined by the flux-current loop of Fig. 2(D)

$$i = \frac{AT_c}{N} \tag{3}$$

Consecutive voltage pulses will raise the flux level by equal amounts. At the end of the ninth pulse, in this particular case, the core will be at positive residual flux, as indicated by point 9. When the next voltage pulse arrives, the core will be driven into saturation, point 10 in Fig. 2(D). Then the load current is no longer limited by equation 3, but increases substantially to

$$i = \frac{e}{R_L + R_G} \tag{4}$$

The large current pulse is the indication for a completed count; thus we have a counter of 10. The large current pulse can be used, for instance, to actuate a relay, or to provide an input pulse for a second stage of a decade counter.

The memory properties of magnetic cores are also utilized for the storage of information in large-scale computers.[11] For instance, in a binary system, each digit can have only two values, usually referred to as 0 and 1. With one residual flux assigned, e.g. the negative one to indicate 0, and the positive residual flux to indicate 1, the value of the digit can be stored. The time required to change the core from a 0 to a 1, or vice versa

(called flux-reversal time) limits the speed of the computer. For the purpose of minimizing the delay caused by eddy currents, the magnetically active part is often made of ferrite; ultrathin, vacuum deposited magnetic films promise a further reduction of flux reversal time.[12–14]

TIMER

If the counting pulses e, Fig. 2(B), arrive at a constant rate, the counter becomes a timer. Such a device has been used as a weld-control timer, counting up to 50 pulses per core.[15] A tap-changing switch, connecting various numbers of active turns, permits different time settings. Suitable core materials for counting applications are those with rectangular flux-current loops, such as Dynamax,[16] *65*-permalloy, 50-50 anisotropic nickel-iron (listed in sequence of preference). A pulse supply voltage of constant volt-seconds can be obtained from a circuit arrangement such as described in the following section, and shown in Figs. 3 and 4. A multistage, decade-counting device, which takes advantage of transistors, is described in reference 17.

ORDINARY SATURABLE-REACTOR CONTROL

When one winding of the *SR* is connected in series with the supply voltage and the load, and the other winding is connected to a direct-current source, the simplest form of a magnetic amplifier results (Fig. 5). This circuit, particularly in its double-core form, has found widespread attention in practice and literature,[1–8,18,19] but it falls outside the scope of this paper, as indicated in the synopsis. It will merely be mentioned that this circuit is not only used as a power amplifier, but also as a constant-current source, a-c limiting reactor, phase shifter, frequency doubler, and measuring device for large direct currents and high direct voltages. While the above list of properties is also exhibited to some extent by the single-core arrangement of Fig. 5, the greater efficacy of the double-core arrangement makes it the preferred form for practical applications.

CORES WITH MULTIPLE-FLUX PATHS

Since cores with multiple-flux paths (e.g. Transfluxor) are outside the scope of this paper their discussion will be found in references 20 through 22.

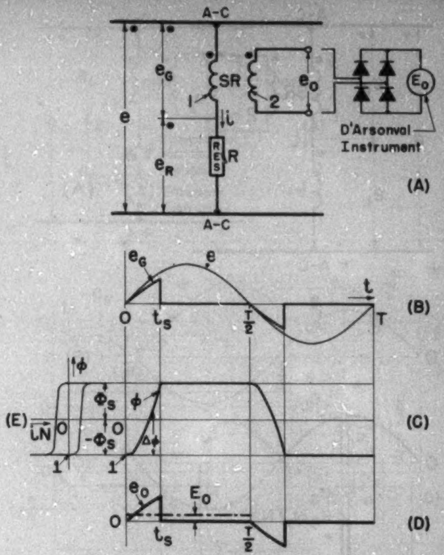

Fig. 3. Voltage or current reference circuit

D—Output voltage e_O
E—Flux-current loop

SR+Resistor R

FREQUENCY DETECTOR

Let us connect an *SR* across an a-c bus, Fig. 3(A). The resistance of winding 1 is lumped into *R*. Suppose the core flux ϕ is at negative saturation at $t=0$ (points 1, Figs. 3(C) and (E). For $t>0$, the supply voltage e becomes positive, Fig. 3(B), and the core leaves negative saturation. The core flux increases according to equation 1. A magnetizing current will flow, causing a voltage drop on the circuit resistance *R*, thus the gate voltage e_G may be smaller than the supply voltage e. Hence,

$$\Delta\Phi=\frac{10^8}{N}\int e_G dt \tag{5}$$

The output voltage e_O, Fig. 3(D), follows from

$$e_O=e_G N_2/N_1 \tag{6}$$

The average output voltage E_O for the first half-cycle is

$$E_O=\frac{2}{T}\int_0^{\frac{T}{2}} e_O dt \tag{7}$$

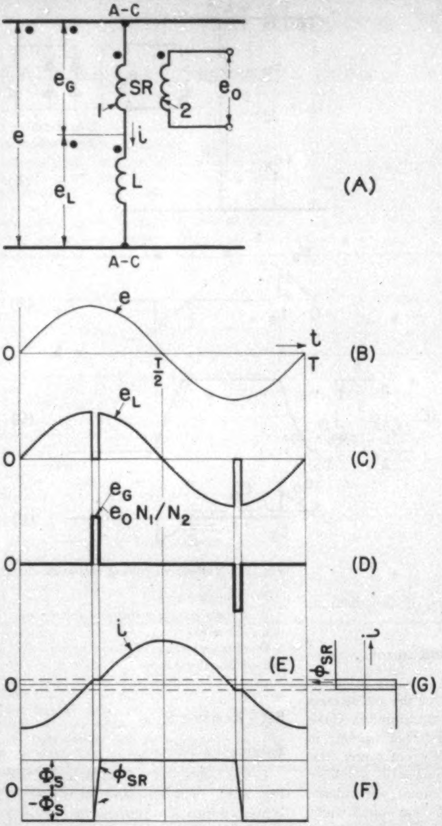

Fig. 4. Peaking circuit

A—Circuit diagram
B—Supply voltage
C—Voltage on inductor L
D—Gate and output voltages
E—Current in winding 1 of SR
F—Flux in SR
G—Flux - current loop for core of SR

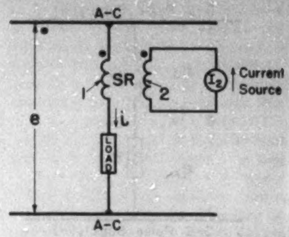

Fig. 5. Ordinary saturable-reactor control

At $t=t_s$, the core is said to saturate, $\Delta\Phi=2\Phi_s$, Fig. 3(C), and it will be assumed that the core will remain saturated for the remainder of the half-cycle. Hence

$$E_O=\frac{2}{T}\;\frac{N_2}{N_1}\int_0^{t_s} e_G dt \tag{8}$$

Substituting from equation 5 into equation 8, and for $\Delta\Phi=2\Phi_s$,

$$E_O=4f\Phi_s N_2 10^{-8} \tag{9}$$

where the supply frequency f replaces the period T. The events during the second half-cycle produce similar results. A D'Arsonval instrument energized through a loss-free rectifier, Fig. 3(A), will read E_O.

One concludes that the output voltage E_O is proportional to the supply frequency. The output voltage E_O is not affected by the magnitude of the supply voltage, as long as the core saturates at least once in each half-cycle. The wave shape of the supply voltage e is irrelevant as long as it does not go through zero more than once per half-cycle. The magnitude of the resistance R does not affect E_O, it merely controls the maximum value of current i (equation 4). If a current flows in the output circuit, the output voltage E_O is only reduced by the voltage drop in winding *2* of the *SR*, but is not affected by the voltage drop in *R*. As long as the saturation branches of the flux-current loop, Fig. 3(E) are horizontal in the first and third quadrants, the width of the flux-current loop and the shape of its flanks are irrelevant to the operation of the circuit.

Practical applications of this circuit are made for frequency regulators, frequency compensators, over-frequency, and under-frequency indicators and controllers.

VOLTAGE OR CURRENT REFERENCE

If the supply frequency f is constant, the output voltage E_O (equation 9) is also constant, and the circuit, Fig. 3(A) can be used as the basis for a voltage or current reference circuit.[23] If the supply frequency is variable, frequency compensation can be applied, by, for instance the addition of linear reactors in the output circuit.[24,25] Reference 25 describes a circuit which holds the output current at 15±.02 ma (milliamperes) d-c, while the load is 50 ohms, the supply voltage varies from 100 to 140 volts, the supply frequency varies from 360 to 440 cps, and the temperature varies from −55 to 100 C (degrees centigrade). The device has a volume of 15 cubic inches and weighs 1.5 pounds.

FIRING CIRCUITS FOR THYRATRONS

For the precise firing of grid-controlled mercury arc or gaseous rectifiers, a rapid rise of the grid-cathode voltage is needed. Such a voltage develops across the resistor *R*, Fig. 3, at the instant t_s of core saturation. This voltage e_R can be applied directly, or by interposition of a so-called grid transformer to the grid-cathode circuitry.[26]

SR+Linear Inductor L

PEAKING CIRCUIT, FREQUENCY MULTIPLIER

Let us replace the resistor *R* of Fig. 3(A) by a linear inductor *L*, as shown in Fig. 4(A). In order to emphasize the fundamental action of this circuit, let us assume zero resistance for all circuits, and an

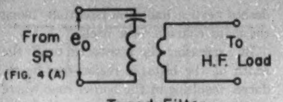

Fig. 6. Frequency multiplication through tuned filter

ideal, square flux-current loop for the core material of the *SR*, Fig. 4(G). It will be seen from an inspection of the various wave shapes shown in Fig. 4 that the supply voltage e appears as the gate voltage e_G, and hence produces the output voltage e_O at or near the crest value of the supply voltage e, thus making this circuit far more effective for the generation of short pulses than the circuit of Fig. 3(A).

The output voltage E_O may be used for a variety of applications, for example where fixed input volt-seconds are needed (viz. the counter and the timer, described in the first section of this paper). The pulses can also be used for the grid control of thyratrons. Furthermore, the substantial content of higher harmonics of the pulses can be utilized for frequency multiplication. By interposing a tuned filter between the *SR* and the load, as shown in Fig. 6, a current having the resonance frequency of the filter will flow in the load circuit. It is obvious from the function of the circuit that the filter is shock-excited, and hence the high frequency voltage will be of damped character. This method of frequency multiplication was used in the early days of radio telegraphy, where supply frequencies of 5 to 10 kc were available, which were stepped up by a factor of 15.

Connecting a linear capacitor in series with the linear inductor L of Fig. 4(A) increases the circuit efficiency to 50% when multiplying the supply frequency by a factor of 47.[27]

Other methods of frequency multiplication involve multiple magnetic cores, and hence fall outside the scope of this paper. For the reader who is interested in frequency multipliers, see references 28 through 34.

SR+Nonlinear, Symmetrical Resistor

DIRECT CURRENT WITHOUT RECTIFIERS

The circuit consists of an *SR*, Fig. 7(A), whose control circuit is energized from a d-c source I_2. A symmetrical, nonlinear resistor is connected in series with the gate circuit.[35] A suitable nonlinear, symmetrical resistor may be made of carbon, or silicon-carbide such as is known as Thyrite.[36] The provision of a current source, rather than a voltage source, for the energization of winding 2 leads to a smooth current I_2 as shown in Fig. 7(C). The action of the load current i can be traced from the Figs. 7(D) and (G). (A detailed description of a related circuit action can be found in Chapter 8 of reference 8). The core saturates at t_s; that is, when the flux upswing equals the flux down-swing, Fig. 7(E). One sees from Fig. 7(B) that areas

$$B=C+D \tag{10}$$

During the interval $t_s<t<T$, the core is saturated; hence $e_R=e$. The volt-seconds acting on the nonlinear, symmetrical resistor are expressed by area E

$$E=A+B-D \tag{11}$$

Substituting from equation 10

$$E=A+C \tag{12}$$

One concludes that the positive volt-seconds (E) from $t_s<t<T$ equal the negative volt-seconds ($A+C$) acting on the load from $0<t<t_s$. Then, for a linear load resistance, the resultant positive-load ampere-seconds (dotted section to 8 of Fig. 7(D)) must equal the negative-load ampere-seconds (1, 2, 4), and hence the load current is a pure alternating. If, however, the load resistor is nonlinear, although symmetrical, as shown by its characteristics in Fig. 7(F), the load resistance will in general be smaller during the interval from t_s to T than from O to t_s. As a result, the positive-load ampere-seconds are now larger than the negative-load ampere-seconds, and hence the load current contains a d-c component. The D'Arsonval ammeter shown in Fig. 7(A) will indicate current flow. If the direction of current I_2 is reversed, the d-c component of the load current will also be reversed.

A gradual change of I_2 causes a gradual change of the d-c component of the load current, and hence, the circuit can also be used for amplification purposes.

In addition to the d-c component, the load current also contains a-c components. The ratio of d-c components to a-c components can be greatly increased by using two *SR*s and two nonlinear, symmetrical resistors feeding into a common load. Among other usages, this arrangement has been applied to a magnetometer; see page 466 of reference 8.

It is also pointed out that in those cases where the main application consists in making d-c without rectifiers, a separate source for current I_2 is not necessary for the 2-core arrangement: this current can be obtained directly from the d-c output terminals of the device.

The phenomenon of making d-c without rectifiers is important where temperature variability of present-day rectifiers introduces undue drift, or where high temperatures preclude the operation of rectifiers. There may be other environmental conditions, such as nuclear radiation[37] where the nonlinear, symmetrical resistor offers advantages over conventional rectifiers.

SR+Capacitor C

ALTERNATING VOLTAGE DETECTOR, BISTABLE CIRCUIT

The circuit shown in Fig. 8(A) is called a series, nonlinear resonant circuit.[38,39] In order to derive some insight into the function of this circuit, the following simplified explanation is offered. (For readers interested in a more rigorous approach, see references 40–43.) First let us consider the three circuit elements separately. Beginning with the *SR*, the applied voltage E_G and the current I to the *SR* are related by the curve marked *SR*, Fig. 8(B); current I and all voltages in Fig. 8(B) are expressed in effective (rms) values. Next, the relation between capacitor voltage E_C and current I is shown by the straight line marked *C*. Finally, with the load being assumed purely resistive, the relation between load voltage E_R and current I is shown for two different load resistances by the straight lines marked *R* and *R′*.

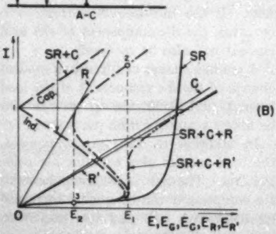

Fig. 8. Ferroresonance

A—Series, nonlinear resonant circuit
B—Voltage and current relations

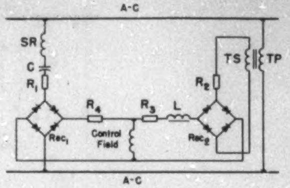

Fig. 9. Voltage-error detecting circuit

Next, let us combine two circuit elements, namely, the *SR* and the capacitor *C*. If the *SR* were a linear inductor, E_G and E_C would be sinusoidal and of opposite phase. With the *SR* actually being nonlinear, E_G and E_C are no longer sinusoidal, but their fundamental components are still of essentially opposite phase. In order to establish the voltage $E_{G,C}$, Fig. 8(A), which is across the series connection of the *SR* and the capacitor *C*, the liberty is taken of obtaining $E_{G,C}$ by subtracting E_C from E_G, resulting in the dashed characteristic labeled *SR+C* in Fig. 8(B). If the current is smaller than is indicated by the distance 0-1, it is inductive; if larger than 0-1, it is capacitive with respect to $E_{G,C}$.

The terminal voltage E is approximated by the vector sum of $E_{G,C}$ and E_R, resulting in $E=\sqrt{E_{G,C}^2+E_R^2}$. Thus, the characteristic marked *SR+C+R* has been determined in Fig. 8(B).

It will be noticed that the characteristic *SR+C+R* is bistable; i.e., when the supply voltage E is increased from zero, the current increases according to the lower branch of the characteristic. If the supply voltage is increased merely a trifle beyond E_1, the load current will increase to point 2. For a further increase of supply voltage E, the load current follows the upper branch of the characteristic. If the supply voltage is now decreased down to E_2, the current will decline according to the upper branch of the control characteristic. However, a minute decrease of the supply voltage E below E_2 will cause the load current to establish itself at point 3. For supply voltages between E_1 and E_2, two stable states for the load current are possible, hence the name bistable circuit. The bistable region is not traversed along the dashed vertical lines, but essentially along the main characteristic itself.

By increasing the resistor R to R' the width of the bistable region can be reduced, resulting in the border case where the loop width becomes zero and the characteristic becomes vertical (the curve marked *SR+C+R′*). With a further increase of load resistance, the characteristic remains single-valued, and its slope decreases.

The steep part of the characteristic (*SR+C+R′*) makes the circuit a useful tool for sensing deviations of the alternating supply voltage. For instance, such sensing is utilized in voltage regulators for alternators (see reference 44 and reference 8, p. 480).

One form of application to an alternator voltage regulator[45] is shown in Fig. 9. The control field (to be acted upon by the nonlinear, resonant circuit) may belong to a rotating exciter or a magnetic amplifier which directly or indirectly energizes the field of the alternator. The current flowing through the control field is the difference between a current proportional to the line voltage, and another current coming from the nonlinear resonant circuit, which sharply varies as the supply voltage varies.

The bistable characteristic, *SR+C+R*, Fig. 8(B), is utilized for the handling of logic in digital systems. When this is combined with a second circuit, identical to that of Fig. 8, a trigger pair is obtained, which forms the basic building block for binary counters, storage registers

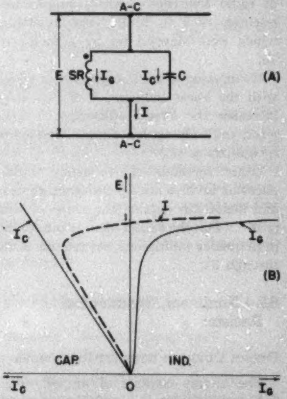

Fig. 10. Ferroresonance

A—Parallel, nonlinear resonant circuit
B—Voltage, current, and phase angle relations

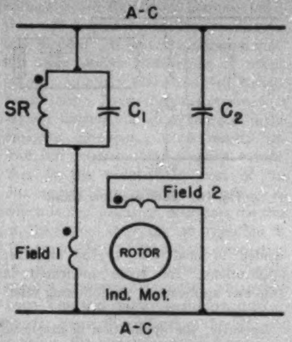

Fig. 11. Reversible induction motor drive

and other logic operations.[46] Triggering is usually achieved by single-polarity pulses which produce simultaneously mmfs (magnetomotive forces) in both cores.

REVERSIBLE INDUCTION MOTOR DRIVE

The circuit of Fig. 10(A) is called a parallel, nonlinear, resonant circuit. The currents through the *SR* and the capacitor *C* are shown in Fig. 10(B). Because of the phase opposition between I_θ and I_C, the total current I is assumed to be their difference. If the supply voltage E is larger than is indicated by the distance 1-0, the current I will be inductive; if E is smaller than 1-0, the current I will be capacitive.

Reversible, induction motor drives are often used as control means for line voltage regulators, where they may actuate a tap-changing mechanism of a transformer, or they may actuate an induction-type voltage regulator. If one field of the control motor is connected in series with a parallel, nonlinear resonant circuit (SR-C_1, Fig. 11), and the other motor field is connected in series with a power-factor correction-capacitor C_2, the motor will rotate whenever the supply voltage deviates from the set point. With proper phasing, the motor armature can be made to rotate in such a direction as to have the tap-changing transformer or induction regulator restore the supply voltage to the set point.

FLASHING LIGHTS, SUBHARMONIC OSCILLATOR

In reference, again, to the circuit of Fig. 8(A), if a d-c bias is applied to another winding of the *SR* (not shown), the circuit may break into subharmonic oscillations.[47] The period of oscillation can be varied by variation of the bias over a range of from several cycles to several seconds. This tendency to break into subharmonic oscillations is useful in flashing lights of railroad-crossing signals, or flashing beacons, and other applications requiring pulsating energization. As this circuit uses exclusively static means for switching, its maintenance is reduced to the barest minimum.

For further study of subharmonic oscillators see references 48 through 50.

SR+Capacitor C+Linear Reactor L

LINE VOLTAGE STABILIZER, FREQUENCY SENSOR

As long as the *SR* saturates twice in each cycle (see section on the frequency detector), the average gate voltage across the *SR* will remain fairly constant (equation 9). When the load resistance R is connected in parallel to the *SR* as shown in Fig. 12, the average value of the load voltage E_R will also remain fairly constant. In order that the difference between the variable supply voltage E and the average load voltage E_R be taken up, a linear inductor L is provided for.[51]

As indicated, the load voltage E_R is not perfectly constant, but it will change slightly in the same direction as the supply voltage changes. In order to counteract this variation, a voltage is added to the load circuit, which will decrease the load voltage when the supply voltage increases, and vice versa. Such a voltage can be introduced into the load circuit by connecting the load to tap *2* of the linear inductor L, instead of to tap *1*. The capacitor C improves the regulation properties of the circuit, and affects the wave shape of the output voltage.

Line voltage stabilizers, using the above principle, are commercially available for output powers of a few watts or up to many kilowatts. The output voltage usually is held within ±1% of rated voltage for supplying voltage variations of ±15%. In most commercial stabilizers the output circuit is isolated from the supply circuit. The speed of response of the circuit is usually such as to correct for line voltage fluctuation in less than two cycles. Another important feature of this circuit is the inherent limitation of line currents when there are short circuits in the load circuit.

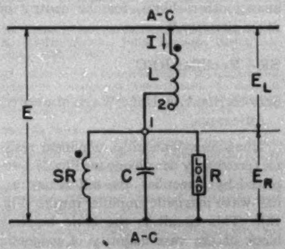

Fig. 12. Basic circuit for line voltage stabilizer

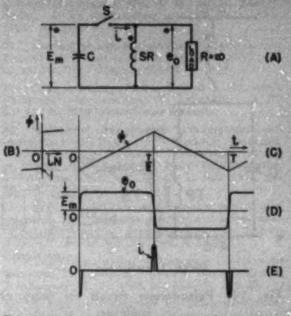

Fig. 13. Square-wave constant-voltage power supply

A—Simplified circuit part
B—Flux-current relation
C—Core flux
D—Output voltage
E—Current between C and SR

As the supply frequency changes, the number of pulses of fixed volt-seconds, as controlled by the *SR*, will also change; hence the load voltage becomes frequency-sensitive (equation 9). In cases where this sensitivity is undesirable, frequency compensators can be supplied.

However, there are applications, as discussed under "Frequency Detector," where the object is to indicate or control the supply frequency. In these cases the load current of the voltage stabilizer is compared with a current derived directly from the same voltage via a fixed impedance, the difference between these currents being the error signal. A circuit similar to that shown in Fig. 9 would be useful. For a fixed supply voltage, the output voltage of the stabilizer will increase by about 1.5% for an increase of 1% of the rated supply frequency.

SQUARE-WAVE, CONSTANT-VOLTAGE POWER SUPPLY

The designer of a voltage stabilizer has several means of affecting the wave shape of the output voltage. In most

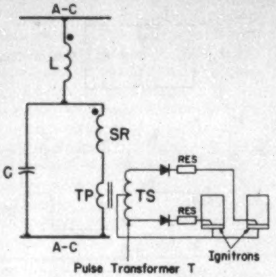

Fig. 14. Pulse-former circuit for firing of ignitrons

cases he will attempt to obtain a sine shape. There are, however, cases where a square voltage is more desirable, one in point being a power supply for magnetic amplifiers whose control characteristics should be inherently linear.[52]

The output voltage E_R (Fig. 12) can be made fairly square by using a square-loop core material and toroidal construction for the *SR*. The following is intended as a simplified explanation of the function of the circuit.[53,54] The core material of the *SR*, Fig. 13(A), is represented by the flux-current relation shown in Fig. 13(B). The load resistance *R* is assumed to be infinitely large, the switch *S* is open, and capacitor *C* has been charged to a potential of E_m volts. The core of the *SR* has been set to point *1* of Fig. 13(B).

Let us now close the switch *S* at $t=0$. The voltage E_m is now applied to the *SR*, and its core flux ϕ increases according to

$$\phi=-\Phi_s+\frac{10^8}{N}\int E_m dt \qquad (13)$$

By assuming zero width of the flux-current loop of the core, and infinite resistance for the load, no current will be drained from the capacitor *C;* hence the output voltage $e_0=E_m$. The flux ϕ increases linearly, as shown in Fig. 13(C). At $t=T/2$, saturation is reached. The only impedance in the discharge path of the capacitor *C* is assumed to be derived from the air flux of the *SR*. A sinusoidal current *i* of very short duration will flow, Fig. 13(E), transferring the electrostatic energy of the capacitor into electromagnetic energy of the air field of the reactor, and then returning this air field energy to the capacitor *C*, which results in a voltage reversal of the capacitor. Under the influence of $-E_m$ the core of the *SR* will now decrease its flux linearly until $t=T$, where another reversal, similar to the one described above, takes place. Since the losses for this circuit are assumed to be zero, this oscillation will continue, resulting in an output voltage of e_0 of nearly square-wave shape.

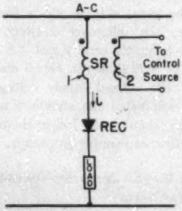

Fig. 15. Self-saturated half-wave magnetic amplifier

If the circuit of Fig. 13 is connected, by means of a linear inductor *L*, to an alternating supply voltage (resulting in the circuit previously shown in Fig. 12), continuous generation of square waves is assured. At the same time, the constant voltage properties of this circuit are retained. It should be pointed out, however, that the flow of output current into the load, causes a deterioration of the squareness of the output voltage.[53,54]

Pulse-Former Circuit, Firing of Ignitrons

It has been shown in Fig. 13(E) that a sharp current pulse flows between capacitor *C* and *SR*. This pulse can be utilized for the firing of ignitrons, as shown in Fig. 14. The circuit will be recognized as derived from Fig. 12, by a connection of the primary *TP* of a pulse transformer in series with *SR*. The secondary *TS* of the pulse transformer energizes the ignitors via rectifiers and resistors.[55] Rectifiers are used to avoid damage of the ignitors by reverse current.

The circuit shown in Fig. 12 also serves as the starting point for so-called "pulse-sharpening circuits," which are used, among other things, for the control of radar circuitry.[55]

SR+Rectifier REC

Self-Saturating Half-Wave Magnetic Amplifier

When the symmetrical, nonlinear resistor (previously described; see Fig. 7) is replaced by a rectifier, the self-saturating, half-wave magnetic amplifier results (Fig. 15). This circuit is the basic building block of the vast majority of magnetic amplifier applications.[56-60]

As stated in the synopsis, it is not intended to deal with typical amplifier applications; for those interested in amplifier applications the following references are listed: 1–10, 61, and 62.

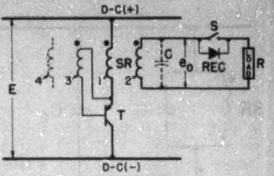

Fig. 16. Basic oscillator circuit

Recently, the application of magnetic amplifiers to static switching applications has been revived. Since the operation of many of these switching applications is analogous to typical magnetic-amplifier operation, merely references to static switching applications are listed here: 39, 47, 63–68.

Cores and rectifiers are also used increasingly in computers and in digital information-handling equipment. As these circuits usually use a plurality of cores and rectifiers their discussion falls outside the scope of this paper. For the reader who is interested in this field, references 69 through 73 have been prepared.

SR+Transistor T

Oscillator, Frequency Modulator

An *SR* is connected in series with a transistor *T* as shown in Fig. 16. The winding *2* of the *SR* is connected to the load resistor by means of the closed switch *S*.[74]

Let us assume that the core of the *SR* is unsaturated. If the direct supply voltage is now applied to the circuit, the transistor will pass some current, and part of the direct supply voltage will appear as a positive voltage across winding *1* of the *SR*. This voltage is transformed into winding *3*, which provides positive feedback and makes the transistor fully conducting. A positive output voltage e_0 is induced simultaneously in winding *2*, and also charges the distributed winding capacitance of the *SR*, indicated by *C*.

When the core flux reaches the positive knee of the flux-current loop, the voltage induced into winding *3* will become smaller, causing the emitter-collector resistance of the transistor to go up. This process is cumulative to the point where the voltage across winding *1* will even reverse (that is, become negative), in order to maintain its state of magnetization according to Lenz' Law. The

Vol.
Pt. 1
1958

voltage on winding *3* also becomes negative, and current flow in the transistor is now blocked. However, a negative voltage also appears on winding *2*, which is able to carry a current to satisfy Lenz' Law. Thus, the capacitance C is rapidly discharged, and recharged in the opposite direction. As a result, the core flux returns from positive saturation to the unsaturated part of the flux-current loop. The output voltage e_0, which is now negative, decreases the flux in the cores according to equation 2. The transistor is blocked from conduction by winding *3*. The core flux finally reaches negative saturation, whereupon Lenz' Law will cause a positive voltage to appear across all windings of the *SR*. As a result, the transistor again turns fully on, and completes the cycle of operation, producing alternating current in the load resistor R.

If a series of unidirectional pulses in the load resistor is desired, switch S is opened, and thus rectifier *REC* becomes effective.

The frequency of the oscillator can be controlled over a range of 3 to 1 by varying the direct supply voltage E.[74] A different manner of varying the frequency consists in introducing a d-c control signal to the fourth winding of the *SR*.

An *SR* can be combined with two transistors to form a square-wave oscillator, which, among many applications, can be used to energize magnetic amplifiers.[75–79]

Combinations of transistors and magnetic cores are used in computer engineering.[71,80,81]

Conclusions

The combinations of a saturable reactor with other circuit components produce extraordinary effects which, in general, cannot be duplicated by linear circuitry. While many of these effects have been utilized in the past, it is the hope of the author that this paper will stimulate further study, development, and utilization of nonlinear magnetic circuitry.

◆

Discussion

H. J. McCreary (General Telephone Laboratories, Inc., Northlake, Ill.): This paper is a very timely review of the field of nonlinear magnetics. Since some of my pioneering work is cited in references 9 and 21 of the paper, perhaps some of my more recent work should be of interest to those pursuing this subject. In addition to the material cited are my U.S. patents: nos. 2,567,116, 2,602,153, 2,611,119, 2,611,120, and 2,623,205.

Of particular interest should be U.S. Patent no. 2,703,388, covering the magnetic cross valve used as an amplifier. Also of probable interest to those in this field is a recent paper which I presented at the 1957 National Electronics Conference, "The Magnetic Memory Switch or Madget Register Storage Device." This is a new method of data storage which has created considerable interest because it is more simple and direct than any other known means.

An Experimental Study of a Binary Code

W. W. PETERSON
ASSOCIATE MEMBER AIEE

ELIAS HAS DESCRIBED a coding system which consists essentially of iterating the Hamming code[1] and has obtained estimates of the probability of error after each iteration on the assumption that each set of check bits is used once and then discarded. It seemed that the first set of check bits could be reused profitably after some errors were corrected with the second set of check bits but the analysis is seriously complicated by the interdependence of errors. Therefore an experimental study of codes of this type was made using the IBM *704*. Matrices of 8 by 16, 16 by 32, and 32 by 64 bits with Hamming single-error correcting, double-error detecting codes in each column and each row, were used. Errors were introduced randomly, and the Hamming correction procedure was then applied alternately to rows and columns. The results of the experiment and some properties of the code pertinent to their discussion are described in this paper.

The Code

Information is assumed given in the form of rectangular matrices of binary digits. Columns of check digits are added to these arrays to make each row conform to the Hamming single-error correcting, double-error detecting code. Then rows of check digits are added to make each column conform to the Hamming code. It may be shown that the new rows conform automatically to the Hamming code so that a system of parity checks may be applied to every row and every column to correct and detect errors.

In the experiments, matrices of only three sizes were used: 8 by 16, (4-by-11 information bits), 16 by 32 (11-by-26 information bits), and 32 by 64 (26-by-57

Paper 58-38, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 15, 1957; made available for printing January 2, 1958.

W. W. Peterson is with the University of Florida, Gainesville, Fla.

The work described was carried out at the International Business Machines Corporation research center, Yorktown Heights, N. Y. This problem was suggested by Peter Elias, who contributed a number of valuable ideas, including the method for comparing codes. Jake Johnson wrote the most difficult part of the *704* code, that which actually covers the parity check and Hamming correction on a set of rows or columns.

TABLE I. ARRANGEMENT OF PARITY CHECKS FOR HAMMING CODE

information bits). If the rows or columns are numbered starting with zero, the check bit rows or columns are numbered, for convenience, 0, 1, 2, 4, 8, 16, and 32. The arrangement of parity checks for a row of length 8 is shown in Table I. The X's under a given check column number indicate which columns are included in that parity check, and the check bit is chosen to make the total number of ones in columns included in that parity check even. The arrangements for larger rows and columns are the obvious extensions of Table I.

Information with parity checks is assumed to be sent through a noisy channel so that certain bits in the array change. At the receiver end, first the parity of each row (corresponding to the parity check column 0) is checked. If that does check, there must either be no errors or an even number of errors. In either case nothing is done. If it does not check, then it is presumed that there is a single error in the row (although there may be any odd number of errors), and the correction is made by calculating the other parity checks and changing the only single bit that could cause the particular combination of parity check failures found to occur.

After this correction procedure is applied to rows, it is applied to columns, then alternately again to rows and columns until nothing more is gained.

The ability of the Hamming code, and hence of this code, to correct errors depends only upon the pattern of errors and not at all upon what the information bits happen to be. This is true of all group alphabets.[2] For simplicity, therefore, the codes were studied with all zeros in the information positions. It followed, then, that initially there had to be all zeros in the parity check positions as well. Thus any ones that remained after correction represented errors.

An example of the operation of the code is given in Fig. 1 for a 4-by-8, all-zero matrix. The errors introduced appear as ones in the unchecked matrix. When the error correction procedure is applied to rows, the second matrix results. The third matrix results after error correction is applied to columns, and the fourth after it is applied once more to rows.

This example illustrates two important facts: First, it demonstrates that after the first check on rows and on columns, additional correction may sometimes be gained by applying the checking procedure to rows again. Second, it shows that a point may be reached where the checking procedure described in this paper will produce no change in the matrix, since further operations on the fourth matrix will have no effect. Another type of stalemate in this checking procedure is illustrated in Fig. 2. A check on rows in matrix (*a*) will result in matrix (*b*), while a check on columns in (*b*) will result in (*a*) again.

This code has minimum distance 16,[3] since the smallest pattern of errors resulting in no parity check failures is a pattern including all the intersections of four rows and four columns. It therefore has the potential ability to correct any pattern of fewer than one half of 16, or 8, errors. The procedure described does not do this, however. Patterns of four errors left uncorrected by this procedure result in exactly two parity check failures in rows and two in columns. They may be corrected simply by changing the digits at the four intersections. Strangely, patterns of six errors may also be corrected by a similar procedure. They manifest themselves in the failure of parity checks in three rows and in three columns. Changing all bits of intersections will correct six errors and produce three errors, but the three new errors may be corrected by applying the correction procedure, at most, twice.

The error probability after the correction procedure has been applied once to rows may be estimated by the method used by Elias.[1] Because single errors are corrected, even multiple errors remain unchanged, and odd-multiple errors result in the addition of no more than one error:

$$Np_1 \leq \sum_{i=2,\ \text{even}}^{\leq N} ip(i) + \sum_{i=3,\ \text{odd}}^{\leq N} (i+1)p(i) \tag{1}$$

Here N is the number of digits in a row, p_1 is the probability of error per position after correction, and $p(i)$ is the probability of i errors in the N digits before correction. Where p_0 is the probability of error before correction

$$p(i) = \binom{N}{i} p_0^{\,i}(1-p_0)^{N-i} \tag{2}$$

This last expression may be put in the form

$$p_1 \leq \sum_{i=2}^{N} \binom{N}{i} \left(\frac{2i-2^{i-1}}{N}\right)(-p_0)^i \tag{3}$$

The first term is used by Elias as an upper bound on p_1. The terms alternate in sign, and therefore the sum of the first k terms for any odd k is an upper bound. Usually p_0 is small enough so that all but the first one or two terms are negligible. For small p_0 the equation gives a close estimate of probability of error: it may be shown that the correction procedure always converts a triple error into a quadruple error, and that therefore there is no approximation in the equation up to and including quadruple errors.

The error probability after correction has been applied to columns the first time may be estimated by this same procedure, since the probabilities of errors in the positions in any one column will be independent. In equation 3, p_1 should be used in place of p_0, and N should be taken as the number of digits per column. After correction has been applied on rows for the second time, however, the procedure breaks down because there is no longer statistical independence of the bit positions. Trying to account for the dependence appears altogether too complicated and so does trying to predict which error patterns are correctable and which are not. One way out of this impasse is an experimental evaluation.

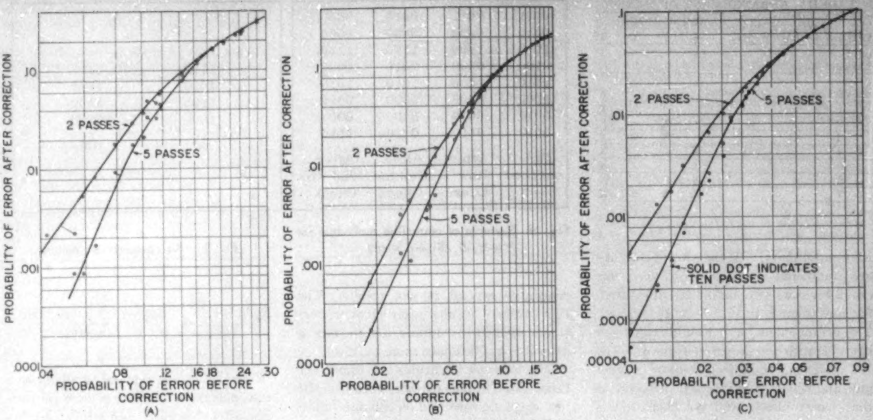

Fig. 3. Probability of error after correction

A—For an 8-by-16 matrix

B—For a 16-by-32 matrix

C—For a 32-by-64 matrix

The Experiment

For the experimental work, the IBM *704* subroutines were written to form a matrix with random errors, to count errors and print totals, to go through the Hamming correction procedure on rows or columns, and to print an entire matrix. The last subroutine was used only for checking the correction and error-counting routines on a number of examples.

Each 32-by-64 matrix consisted of a single bit in corresponding bit positions in each of 2,048 *704* words. Since each *704* word has 36 bits, the block of 2,048 words stored 36 matrices. The routine which formed the matrix first cleared the bits in all matrices to zeros, since the information bits were always made zeros in the experiments. Then for each bit in each matrix a pseudorandom number between zero and one was calculated by the currently popular method, and an error was introduced if the number was less than p_0. Successive powers of 5^{13} modulo 2^{35} were used.[4]

The method of storing the matrices enabled simultaneous calculation of parity checks for 36 matrices using the AND, OR, and COMPLEMENT instructions of the *704*. On the basis of the parity checks, the decision is made, for one matrix at a time and for one column or row at a time, as to whether and where correction should be made. For 32 by 64 matrices, the complete checking procedure applied once to rows or to columns of the 36 matrices required roughly 6 seconds.

The error-counting routine examined each bit in each matrix, one matrix at a time, and printed the total number of ones in each matrix (which was also the total number of errors, since the correct information and parity check bits were all zeros). It also printed the average frequency of error for all 36 matrices. A complete print-out required 10 seconds.

A typical experiment consisted of the formation of a matrix and printing of the number of errors before correction, followed by 10-correction cycles, each followed by a print-out, alternately, on rows and columns. A total of about 205 seconds was required for the 36 32-by-64 matrices.

Discussion of Results

The plots of average probability of error after decoding, Fig. 3, represent the most important results. For each point the abscissa is the percentage of positions (including check positions) with errors before correction, and the ordinate is the percentage of all positions (also including check positions) with errors after correction. In each case the upper curve gives error probability after the correction procedure is applied once to rows and once to columns. The lower curve corresponds to correction applied alternately to rows and columns a total of five times (three times to rows).

In Fig. 3(C), the graph for 32-by-64 matrices, a few points, shown as solid dots, are given for correction procedure applied ten times. For the 16-by-32 and 8-by-16 matrices, shown in (B) and (A), the points for ten passes were not plotted because they would lie so close to the points for five passes as only to cause confusion. It appears that there is little to be gained after the fifth pass, especially for the smaller matrices, where the difference was greater than 10% in only a few cases.

The improvement in probability gained by using five instead of two passes is greatest in the low probability range, amounting to as much as a factor of five. As the probability of error before correction increases, the difference gradually decreases until the curves meet at a point where the probability is about one third greater than the reciprocal of the matrix width. At that point, however, the probability of error after correction is approximately as great as the probability of error before correction, and the code would certainly not be used.

Equation 3 gives an upper bound for the probability of error after one pass, say, on rows. An upper bound on the probability of error after two passes may be determined by putting the result back into equation 3 with the appropriate value of N. Since the approximation in deriving equation 3 affected only sets of more than four errors in a row or column, the equation would be expected to yield an error probability that is in good agreement with experimental results after two passes. It does, in fact, give values which agree within 10% everywhere and 2% at most points with the upper curves in Fig. 3.

This equation cannot be used to estimate probability of error after three or more passes because the errors are no longer independent.

Elias has given upper and lower bounds for the probability of error for the best binary block code, given the total number of bits, the number of information bits, and the probability of error for the channel.[5] The values for the bounds are listed in Table II for codes corresponding to the points at which these matrix codes are most efficient in the sense defined in the next section. The optimum code corresponding to the 8-by-16 matrix code has error probability lower by only about a factor of five. For the larger matrices, however, the difference amounts to several orders of magnitude.

Some data on the frequency of error patterns of various sizes are given in Table III. For small probability of error before correction, patterns of four and six errors predominate. It is noted in the section "The Code" that all patterns of four or six errors may be corrected, though not by the Hamming correction on rows and columns.

Data on the number of passes required to bring a matrix to its final condition are given in Table IV for a few cases. In general, more passes are required when there are many errors than when there are few, and in only a relatively small number of cases were more than five correction passes required.

Two kinds of final conditions were noted: those with a constant and those with an oscillating number of errors. A constant number did not imply a constant pattern of error; the illustration in Fig. 2 is a case in point. The number of matrices in which the number of errors was observed to oscillate is indicated in Table IV for the cases presented. In general, the oscillation was more common when there were many errors. It was also noted that when there was oscillation, the smaller number of errors usually occurred after correction on rows, i.e., after an odd number of correction passes. This is quite reasonable because rows were shorter than columns and the Hamming check thus had more error-correcting ability on the rows.

A Method of Comparing Codes

A method of comparing two codes that differ in rate and error probability would be extremely useful. The following measure, suggested by Elias, seems quite appropriate, though without obvious theoretical basis. The quantity α, defined by the following equation, measures the efficiency of a binary code in some sense:

$$\frac{N_1}{N_2}=\left(\frac{1-H(p_2)}{1-H(p_1)}\right)^{\alpha} \qquad (4)$$

where N_1 is the number of binary symbols in a block before decoding, p_1 is the probability of error for any symbol before decoding, N_2 is the number of information symbols after decoding, p_2 is the probability of error for any symbol after decoding, and H is the entropy function.

Since information rate cannot be increased by a decoding operation[6]

$$N_1[1-H(p_1)] \geq N_2[(1-H(p_2)] \qquad (5)$$

and since $N_1 \geq N_2$, it follows that α is at least one. Furthermore, α equals one if, and only if, the equality in equation 5 holds, i.e., if no information is lost in decoding. It is clear that if N_1, N_2, and p_1 are the same for two different codes, then the one with the smaller p_2 is the better, and from equation 4 it may be seen that the better code has the smaller α.

Suppose that two codes had been used in cascade, the first to convert blocks of N_3 into respective blocks of N_2 symbols and the second to form a block of N_1 symbols from each N_2 block. Sending a block of N_1 symbols over a noisy channel then results in errors with probability p_1. Decoding to blocks of N_2 symbols results in probability of error p_2 and efficiency α_1. And further decoding to blocks of N_3

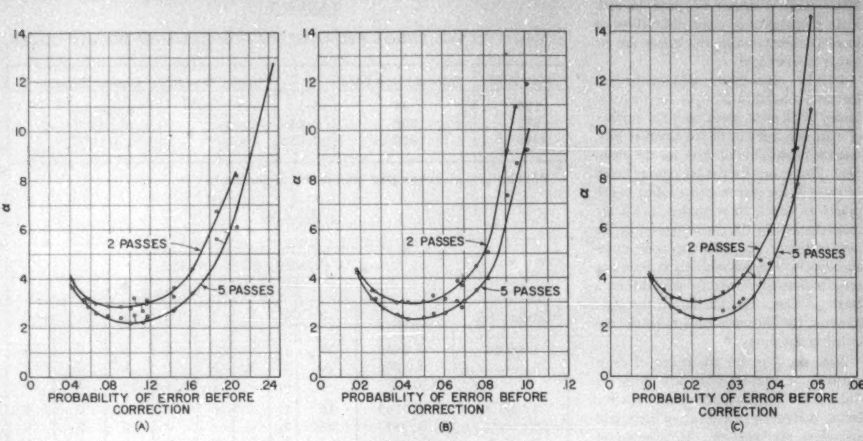

Fig. 4. Efficiency parameter α

A—For an 8-by-16 matrix

B—For a 16-by-32 matrix

C—For a 32-by-64 matrix

symbols results in error probability p_3 and efficiency α_2 for this second step. If $\alpha_1=\alpha_2$, the over-all α turns out to equal α_1 since

$$\frac{N_1}{N_3}=\frac{N_1}{N_2}\frac{N_2}{N_3}=\left[\frac{1-H(p_2)}{1-H(p_1)}\right]^{\alpha_1}\left[\frac{1-H(p_3)}{1-H(p_1)}\right]^{\alpha_1}$$
$$=\left[\frac{1-H(p_3)}{1-H(p_1)}\right]^{\alpha_1} \qquad (6)$$

If $\alpha_1\neq\alpha_2$, the over-all α may be found by an averaging process in which each α is weighted in proportion to the amount the corresponding code decreases the logarithm of the rate per binary symbol:

$$\alpha=\frac{\log N_1-\log N_3}{\log\,[1-H(p_3)]-\log\,[1-H(p_1)]}$$
$$=\left\{\frac{\log N_1-\log N_2}{\log\,[1-H(p_2)]-\log\,[1-H(p_1)]}\right\}\times$$
$$\left\{\frac{\log\,[1-H(p_2)]-\log\,[1-H(p_1)]}{\log\,[1-H(p_3)]-\log\,[1-H(p_1)]}\right\}+$$
$$\left\{\frac{\log N_2-\log N_3}{\log\,[1-H(p_3)]-\log\,[1-H(p_2)]}\right\}\times$$
$$\left\{\frac{\log\,[1-H(p_3)]-\log\,[1-H(p_2)]}{\log\,[1-H(p_3)]-\log\,[1-H+(p_1)]}\right\}$$
$$=\alpha_1\lambda+\alpha_2(1-\lambda) \qquad (7)$$

where

$$\lambda=\frac{\log\,[1-H(p_2)]-\log\,[1-H(p_1)]}{\log\,[1-H(p_3)]-\log\,[1-H(p_1)]}$$

Thus for cascaded codes the efficiency parameter α may be calculated in a convenient manner from the α's for the individual codes.

The values of α for the experiments run on the IBM *704* are plotted in Fig. 4. It is a surprising fact that the minimum (best) α is very nearly the same for all three codes and occurs at an input probability almost inversely proportional to the width of the matrix. The curves are remarkably similar for the three matrix sizes.

Conclusions

Although the code described in this paper falls far short of being optimum for its length, the fact is that no one yet knows how to construct optimum codes except for isolated cases. The code does, however, permit correction procedures that are relatively easy to implement with modern digital techniques, and for that reason should be of more than theoretical interest. By the same token, modern digital computers may prove an important tool for the information theorist in so far as they facilitate experimentation in an area in which little experimental work has hitherto been done.

Magnetic Saturable-Core Timing Device

J. L. LOWRANCE
ASSOCIATE MEMBER AIEE

ACCURATE TIMING DEVICES are fundamentally important in both industial and military control applications. This paper deals with electric timing apparatus in which the timing sense is derived from the volt-second time integral required to saturate a saturable magnetic core. Discrete time periods may be generated on the basis of this principle. In this paper, fundamental design equations are presented and basic circuitry is described. Specific applications are discussed which make use of transistors in the switching mode. Transistors afford convenient means for operating various electric circuits as a function of the time period defined by the controlled saturation of the magnetic cores. The transistors contribute no appreciable time delay in the circuit. The problems associated with environmental variations in transistors and cores are discussed, and possible methods of compensation are presented.

The changes in the magnetic flux level of a magnetic reactor may be related to the volt-time integral of the voltage induced in the windings of the reactor. For fixed values of the other parameters, the time period required to saturate the core is a constant.[1]

$$\Delta T=\frac{2AB_mN}{e}10^{-8} \qquad (1)$$

Therefore a definite time period may be generated using the saturable magnetic core. The accuracy of this time period is is a function of accuracy to which the other parameters are held constant, and the accuracy of sensing the time at which the core becomes saturated. The saturation of the magnetic core is accompanied by a change in the inductance of the saturable reactor. If the core material is of the square-loop variety, this change will be very pronounced. A radical change occurs in the impedance of the electrical circuit associated with the saturable reactor because of this inductance change. The change in impedance can be used to trigger another circuit at the expiration of the time period, when the core saturates.

Type of Core Material

The type of core material used in this application is governed by consideration of several factors. As just mentioned, it is desirable to use a square-loop core material to insure a definite and discrete enunciation in the circuit when the core saturates. The time period is directly related to the cross-sectional area of the core. Therefore it is advantageous to make the saturation flux density of the core as large as possible in order to minimize the size and weight of the saturable reactor.

The magnetic material that most nearly fulfills these qualifications is the 50% nickel, 50% iron alloy. Some commercial names for this alloy are Orthonol, Deltamax, and Orthonik. The coercive force is about 0.06 oersted, and the residual flux may be made between 12,000 and 15,000 gausses.[2] The squareness of the hysteresis loop is quite pronounced in this material. Therefore the core provides the desired sharp change from a high to a very low inductance in the circuit. Fig. 1 shows the d-c hysteresis-loop for Orthonol.

It should be mentioned that cores fabricated as tape-wound toroids afford the best performance. The effective air gap is quite small, permitting the ideal characteristics of the core material to be approached. Since the core is operated on its d-c hysteresis loop, it is not essential that the core have thin laminations. The most desirable core material is a tape thin enough to provide a small effective air gap, yet thick enough to maximize the stacking factor.

Description of Circuitry

The volt-time integral characteristic of the magnetic saturable reactor may be used in various ways to generate a time period or delay interval. Three possible modes of operation will be discussed.

SERIES SATURABLE REACTOR CIRCUIT

For an industance in series with a resistance, the expression for the current flow is

$$E=L\frac{di}{dt}+Ri \qquad (2)$$

If $L>>R$, the current is primarily a function of the magnetizing current of the inductance. This current is

$$I=\frac{Hl_m}{0.4\pi N} \qquad (3)$$

Fig. 2(A) shows a curve of current versus time for a series saturable reactor-resistance circuit. When the core saturates, the current becomes equal to the applied voltage divided by the resistance of the circuit. Putting the saturable reactor in series with the input circuit of a transistor, this change in current may be used to control the output circuit of the transistor. The combined circuit will act essentially as a switch that is shunted by a high resistance in series with a low-impedance load.[3] A grounded emitter transistor circuit is shown in Fig. 3(A). The saturable reactor is initially set to negative saturation by the reset winding N_3. When the switch is thrown to the "fire" position, voltage is applied to the emitter-collector circuit and the Zener diode voltage-regulating circuit.[4] The voltage-regulating

The author wishes to thank J. Frick, L. Peterson, and L. White, of Bendix Products Division, for their assistance in providing experimental models and data used in this paper; and to acknowledge the support of WADC *Contract No. AF 33(600)-303 18*.

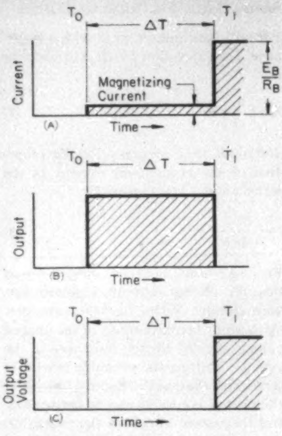

Fig. 2. Three modes of timer operation

circuit, in turn, supplies an essentially constant voltage to the transistor-base–saturable-reactor circuit. This constant voltage is integrated by the saturable reactor until it saturates at a predetermined time T_1. At time T_1, the base current increases and a current flows in the load circuit which is equal to the product of the base current and the current gain of the transistor. The transistor characteristics are shown in Fig. 4. This load current will continue to flow until the input power is removed.

This circuit has one significant disadvantage. The voltage applied to the saturable-reactor–transistor-base circuit is a function of the impedance in parallel with the voltage reference resistor. Prior to saturation of the core, this impedance is much greater than it will be after the core saturates, as shown by the increase in base current. Therefore the voltage source to the transistor-base–saturable-reactor circuit must have a much lower source impedance than the input impedance of the transistor-base–saturable-reactor circuit. If such is not the case, the voltage across the input circuit will drop when the core saturates. This condition, in turn, requires that the voltage integrated by the core be greater than the voltage required to turn on the transistor switch. For a given time period, the core would have to be larger. Therefore, care should be taken in the design of the reference circuit to insure a low reference output impedance. This objective may not be practical because of the limited voltage ratings of presently available "Zener reference diodes."

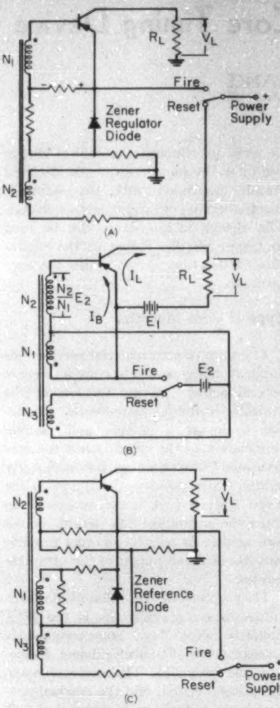

Fig. 3. Time delay circuit

A—See Fig. 2(A)
B—See Fig. 2(C)
C—With voltage regulation

Another disadvantage of this series saturable reactor circuit is an undesirable effect of the magnetization current that flows prior to the saturation of the core. This magnetization current also flows in the base circuit of the transistor, and consequently a correspondingly larger current will flow in the load circuit. This magnetizing current may be bypassed by shunting the base-emitter circuit of the transistor, with a resistor. This resistor would also be in series with the saturable reactor. The threshold voltage of the transistor would prevent current flow in the base-emitter circuit during the magnetization period.

A saturating transformer may be used to generate a pulse of voltage for a definite time interval if the impressed voltage is held constant. This pulse of voltage may be used either to turn on a circuit or to keep a circuit turned off for a definite period. Fig. 2(B) shows the waveform of the voltage across the low-voltage winding of the transformer. This phenomenon is used in the circuit shown in Fig. 3(B) to generate a time delay in the transistor circuit.

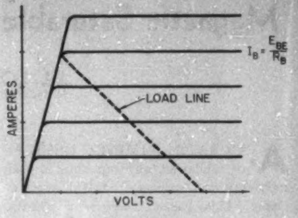

Fig. 4. Typical transistor grounded emitter characteristics

The core is set to one end of the hysteresis loop by the voltage E_2 across winding N_3. At time T_0 the switch is thrown to the "fire" position. The voltage

$$E_2\left[\frac{N_3}{N_1}-1\right] N_3>N_1 \tag{4}$$

appears in the base circuit. The net voltage appearing across the base-emitter circuit is in the direction to keep the transistor turned off. At the time that the core saturates, the voltage across the base-emitter circuit becomes equal to E_2 and the transistor will turn on. The load current will then flow in the output circuit as shown in Fig. 2(C). It is advantageous to make E_2 large enough to saturate the transistor for a given load R_L. This allows the voltage

$$E_1-I_LR_{ce} \tag{5}$$

to appear across the load, and the transistor is thereby operated in its most efficient mode. The saturated junction resistance of the transistor R_{ce}, is quite small for most germanium power transistors. The small value of this resistance allows the transistor to be operated at ambient temperatures near the maximum storage temperature. The transistor will remain on until power is removed from the base circuit. The core may be reset and the timing operation may then be repeated. The reset circuit should be designed so that the voltage reflected into the base-emitter circuit is less than the threshold voltage of the base-emitter circuit of the transistor.

The time period is directly proportional to the voltage absorbed by the core. Therefore a practical circuit application must incorporate some means of regulating the voltage across the winding of the transformer to be sure that the time period will be constant. Fig. 3(C) shows a circuit that uses a Zener diode as a voltage regulating reference device. The voltage across the diode is essentially constant after a certain Zener voltage E_{zr} is reached. This Zener diode regulates the voltage across the timer control winding and the voltage appearing in the base-emitter bias circuit. For most commercially available reference units with zero temperature coefficient, the reference voltage must be attenuated with a resistance network, because of the magnitude of the Zener voltage. Prior to saturation of the core, the impedance of winding N_1 is large compared to its shunting resistor. Therefore the diode voltage will divide according to the resistance ratio shunting the diode. The magnetizing current will flow through winding N_1. This condition will have to be considered if this magnetizing current is large compared to the total current in the attenuating circuit.

Fig. 5 shows a circuit similar to the circuit shown in Fig. 3(C). A 2-stage switching amplifier has been added to the basic timing circuit. When the switch is thrown to the "fire" position, the following events occur:

1. The base-emitter bias circuit of P_1 is energized.
2. The timing voltage across N_1 is applied.
3. Current flows through P_2 in to the load of P_1, turning P_2 on and keeping P_3 turned off. E_L is zero.

At the time that the core becomes saturated, the voltage induced in winding N_2 crops to zero. The base-emitter current of P_1 turns P_1 on. This shunts the base-emitter circuit of P_2. The base potential of P_2 becomes essentially equal to the emitter potential of P_2 and P_2 is therefore turned off. The base of P_3 is no longer at the same potential as its emitter, so it is turned on. Voltage then appears across the load R_L.

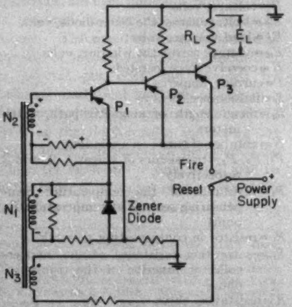

Fig. 5. Three-stage transistor switch and timer circuit

As mentioned previously, the saturable transformer may be used to generate a pulse of voltage of a definite time length. A circuit that performs this function is shown in Fig. 6. Here the voltage induced in the emitter-base circuit is of the polarity to turn on the transistor rather than to turn it off. Therefore the transistor is biased fully on for the period of time necessary for the core to saturate. At saturation, the bias voltage reduces to zero and the transistor is again turned off. This circuit has the disadvantage of drawing power from the control source, which introduces problems of temperature compensation for maintaining a constant reference voltage for the winding. The winding impedance will change as the base-emitter resistance of the transistor varies with temperature, and as the winding resistances of the high-voltage and low-voltage transformer windings vary with temperature. If it is necessary that the circuit be conducting for this period, the stages of transistor amplification may be arranged to turn off rather than on when the time period is being actuated, thereby alleviating the temperature compensation problem.

Magnetic-Field Effect

The time period required to saturate the core is a direct function of the saturation flux density of the core material. It has been pointed out in several current papers that the saturation flux density of magnetic material is a function of the strength of the magnetic field imposed perpendicular to the field of the excitation winding. The net effect is a reduction of the saturation flux density as the perpendicular field strength is increased. The mathematical analysis of this phenomenon may be found in reference 5.

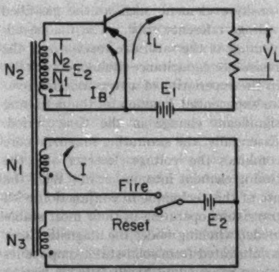

Fig. 6. Pulse output timer circuit

It may be expected that an external magnetic field will have an effect upon the time period of a magnetic timer; this has been found to be a valid assumption. The time required to saturate the core at a given voltage is shortened by the influence of this field. Fig. 7 is a typical curve showing the change in time period as a function of field intensity. Curve *A* shows the effect of a d-c field. Curve *B* shows the effect of the same field intensity with magnetic shielding of cold-rolled steel around the saturable reactor assembly. Curve *C* shows the effect of an a-c field on the same shielded assembly. The choice of location of the timer assembly in the magnetic field is important. The greatest effect is caused by fields parallel to the axis of the toroid. It is felt that the field intensity necessary to affect the time period appreciably is much larger than would be encountered in most applications. If the field were predictable it could be compensated for in the design of the timer.

This field effect is interesting in view of the possible control applications involving this phenomenon. It would be possible to vary the time period as a function of some parameter which controlled the field intensity around the core.

Temperature Effect

The effect of temperature on the time period may be divided into two categories:

1. The change in saturation flux of the core.

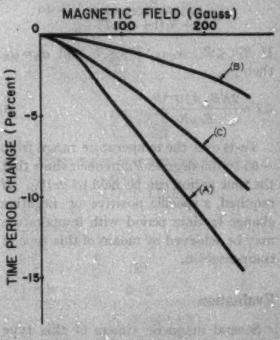

Fig. 7. External magnetic field intensity period

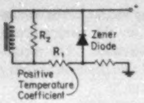

Fig. 8. Temperature compensating circuit

2. The effect of temperature on other circuit components. To some extent, these differences may be made to compensate for each other.

The change in time period is inversely proportional to temperature, causing the temperature coefficient of saturation flux density to be negative. The slope of the curve is not the actual temperature coefficient of flux density, because the increase in cross-sectional area of the core caused by an increase in temperature would tend to compensate for the corresponding decrease in flux density. Nonetheless, the slope of the curve is particularly useful for compensation purposes, since the net effect of the change in B_mA determines the change in the time period.

One way to compensate for the change in time period with temperature is to vary the voltage applied to the core so as to cancel the effect of the change in B_mA. A circuit that achieves this compensation is shown in Fig. 8. The voltage appearing across the winding is

$$E_w = E_{CR}\frac{R_2}{R_2+R_1(1+\alpha_R\Delta T)} \tag{6}$$

This method of compensation is difficult to achieve because of the nonlinearity of the temperature coefficients of both the magnetic material and the compensating resistors. If the temperature coefficients are assumed to be constant, the equation for compensating the time period is

$$\Delta T = \frac{2NB_mA(1-\alpha_B\Delta T)}{E_{CR}\dfrac{R_2}{R_2+R_1(1+\alpha_R\Delta T)}}10^{-8} \tag{7}$$

If $R_2 << R_1$, $\alpha_B\alpha_R\Delta T^2 << 1$, and $\alpha_B=\alpha_R$, then

$$\Delta T \approx \frac{2NB_mA10^{-8}R_1}{E_{CR}R_2} \tag{8}$$

Tests over the temperature range from −65 to 165 degrees Fahrenheit show that the time period can be held to ±1%. If required, a specific positive or negative change in time period with temperature may be achieved by means of this type of compensation.

Evaluation

Several magnetic timers of this type have been fabricated for use in rocket engine controls. Fig. 9 shows a complete unit that provides two time periods, 0.22 and 1.30 seconds. This unit is capable of delivering 5 amperes to an inductive load. The volume is approximately 20 cubic inches and the weight is 1.5 pounds. The following components were used:

Transistors, Honeywell *H-5*, and General Electric *2N187*.

Reference diode, Hoffman semiconductor *1N429*.

Saturable cores, Magnetics, Inc., *51190-4A*, (1.30 seconds); and Magnetics, Inc., *51181-2A*, (0.22 second).

Input voltage, 17 to 29 volts d-c.

The circuitry used is similar to that of Fig. 5 with innovations for temperature compensation and switching of the two time periods in the output circuit.

At a vibration level of approximately 40,000 the 1.30-second time period decreases significantly. This effect is presumably caused by the change in the magnetic properties of the core at this high vibration level because of the mechanical stresses set up in the core material. The shorter time period exhibited essentially stable characteristics over this vibration range. The greater mass of the magnetic core used in the 1.30-second circuit afforded a more significant damping problem than the small core. It was extremely difficult to obtain quantitative data on this phenomenon because of the the difficulty, under these dynamic conditions, of measuring the saturation flux of the core accurately.

Conclusions

The volt-second integral associated with the square hysteresis loop of certain magnetic core materials is a useful and versatile basis upon which to design circuitry for generating discrete time periods. In the past, this field of application was dominated by the use of the time constant of the resistance-capacitance network in conjunction with some voltage-sensitive element such as the gas-filled voltage reference tube. The unique advantage of the saturable reactor over the resistance-capacitance timing network lies in the superiority of a step function over an exponential function as the actuating significant change in the time period. Essentially, the saturating magnetic core combines the voltage detector and the timing element into one unit. With the use of this technique in conjunction with transistors operating in their most stable mode (switching mode), the magnetic timer is fabricated from solid-state components into a rugged and highly reliable timing device. This construction makes the magnetic timer a complementary system component suitable for use with other magnetic and semiconductor control apparatus.

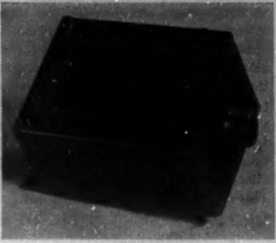

Fig. 9. Fabricated timer unit

The accuracy of device is a function of the compensation provided in the circuitry associated with the saturable core. Temperature compensation may be used to generate timing functions with positive, negative, or zero slope. The size of the timing device is directly related to the desired time period. Therefore the time period is limited, for practical reasons, to less than approximately 10 seconds. Novel circuitry may extend this practical limitation.

Appendix. Nomenclature

A = area of the cross section of the core, square centimeters
α_B = temperature coefficient of saturation flux density, gausses per gauss per C (degrees centigrade)
α_R = temperature coefficient of the resistor, ohms per ohm per C
B_m = saturated flux density of the core material, gausses per square centimeter
e = instantaneous voltage, volts
E = voltage, volts
E_{cr} = voltage across the Zener diode, volts
E_L = load voltage, volts
E_w = voltage across the winding, volts
H = coercive force, oersteds
I = current, amperes
L = inductance, henrys
l_m = mean length of magnetic path, centimeters
N = number of turns on a winding
P_1, P_2, P_3 = transistors of stages 1, 2, and 3 respectively
R_1 = resistance of the temperature compensating resistor at temperature T_0, ohms
R_2 = resistor in compensating network
R_{ce} = saturation resistance of the emitter-collector junction of the transistor, ohms
R = resistance, ohms
t = time, seconds
T_0 = reference temperature, C
ϕ = flux, gausses

Accurate Determination of Capacitance by Conjoining Analytical and Analog Techniques

J. D. HORGAN
ASSOCIATE MEMBER AIEE

J. A. PESAVENTO
ASSOCIATE MEMBER AIEE

THE PRINCIPAL OBJECTIVE of the work described in this paper is to develop a new method for accurately determining the capacitance associated with 2-dimensional composite regions. The term capacitance refers to the ordinary electric capacitance associated with two charged conductors. However, the method is also directly applicable to the determination of the permeance of magnetic fields, to the shape factor of thermal fields, and to other analogous situations. The term "accurately determining" indicates determination of the capacitance with errors in the order of one part in 1,000. While such accuracy has been claimed for certain electrolytic tank analog methods[1] it is usually possible only after careful attention is given to each source of error. Such errors can arise in both the construction and the measurements associated with the analog solution. In the present method electrically conducting paper models, much easier to construct, are used and only ordinary care is required in the measurement techniques. The usual errors encountered in the use of such paper models, amounting to several per cent, are avoided by utilizing analytical methods to obtain a first approximation amounting to perhaps 90% of the final result, and using the paper analogs to determine the other 10%. Thus, the error in the final result will be in the order of a few per cent of, say, 10% or in the order of a few tenths of 1%.

"Two-dimensional region" refers to a region of electric field in the vicinity of two cylindrical (not necessarily circular) conductors or, in other words, a region of which the electric field is independent of one of the co-ordinate variables. A composite region is one which may be divided by means of thin insulating or conducting partitions into two or more simple regions. A simple region is one in which the electrical potential function can be exactly determined by some known analytical method, for example, by use of the Schwarz-Christoffel transformation. Several examples of composite regions are shown in Figs. 1 to 4.

Fig. 1 depicts two parallel rectangular conductors. The quadrant of the 2-dimensional composite region associated with the conductors may be divided by insulating partitions, as indicated by the dashed lines, into three simple regions, each of which may be analyzed for the potential function, with the use of the Schwarz-Christoffel transformation. The strip transmission line of Fig. 2 is associated with a composite region which may be similarly divided. The capacitance per unit length for this configuration has been determined by a series-matching method.[2] The coupled-strip transmission line of Fig. 3 is associated with a more complicated composite region which divides into three simple regions as indicated. The capacitance per unit length for this configuration has been worked out by an analytical method closely related to the method described in this paper.[3] Fig. 4 depicts the problem of the telephone relay, different from the preceding examples because it is a magnetic field problem and because the dividing partition is conducting rather than insulating. This problem has been investigated with the use of an electrostatic analog[4] and by relaxation methods.[5]

These examples serve to illustrate the type of problem for which the new method has been developed. With the use of the present technique, the capacitance of each of these configurations may be determined with errors in the order of 0.1%. In addition, work with this technique yields considerable insight into the magnitudes of the errors associated with the usual first approximations to capacitance obtained by simple partitioning of the field regions.

The Analysis

Explanation of the method can most easily be accomplished by reference to a specific problem. The strip transmission line serves as an excellent example because

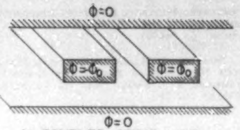
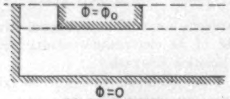
Paper 58-65, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 14, 1957; made available for printing November 22, 1957.

J. D. HORGAN and J. A. PESAVENTO are with Marquette University, Milwaukee, Wis.

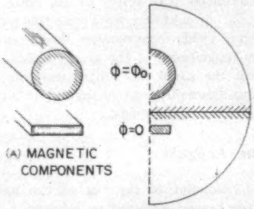


(A) COUPLED-STRIP LINE



(B) QUADRANT

Fig. 3. Coupled strip transmission line



(A) MAGNETIC COMPONENTS

(B) SEMI-PLANE

Fig. 4. Schematic of telephone relay

it is straightforward and because capacitance values have been worked out previously[3] and a check on the accuracy of the method is afforded.

Consider the following problem: Given the strip transmission line of Fig. 2, determine the capacitance per unit length. For simplicity the ground planes are assumed to extend infinitely in the x direction and the dielectric is assumed homogeneous, isotropic, and loss-free. Because of geometrical symmetry, only the quadrant of Fig. 2 need be analyzed.

A first approximation to the capacitance may be made by imagining a thin insulating partition to divide the quadrant into two simple regions. This partition has the property of preventing any component of flux density from existing normal to its surface. The dielectric flux is compelled to follow the surface. With this partition in place, the capacitance per unit length of the quadrant is simply the parallel combination of the capacitance associated with each simple region. For region 1 the capacitance is that of two parallel plates and may be written as

$$\frac{C_1}{\epsilon}=\frac{2w}{a} \tag{1}$$

where C_1 is the capacitance per unit length of region 1 and ϵ is the permittivity of the composite region. For region 2 the capacitance per unit length is derived in reference 3 with the Schwarz-Christoffel transformation. The result is

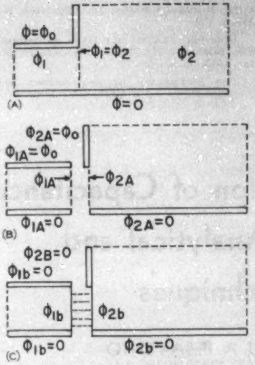


Fig. 5. The compensating fields

$$\frac{C_2}{\epsilon}=\frac{K(k)}{K(k')} \tag{2}$$

where C_2 is the capacitance per unit length of region 2, $K(k)$ and $K(k')$ are the complete elliptic integrals of the first kind, as tabulated, for example, in Dwight[6] and the arguments k and k' are related to the dimensions by

$$k=\cos\left(\frac{\pi a}{2b}\right) \tag{3}$$

$$k'=\sin\left(\frac{\pi a}{2b}\right)$$

The total capacitance per unit length for the strip transmission of Fig. 2 may thus be written

$$\frac{C}{\epsilon}=\frac{8w}{a}+\frac{4K(k)}{K(k')}+\frac{\Delta C}{\epsilon} \tag{4}$$

The first two terms on the right side of equation 4 represent the first approximation to the capacitance and $\Delta C/\epsilon$ represents an increment to be added to account for the presence of the insulating partition. In a previously described method[3] this increment has been determined analytically. In the present method it is determined from measurements on an electroconducting analog.

The Compensating Field

The analog to be constructed will represent a compensating field which accounts for the presence of the insulating partition. The nature of the construction may be understood by referring to Fig. 5, where (A) depicts the composite region which is being investigated, together with the appropriate boundary conditions, and (B) shows the two fields which have been analyzed to obtain the first approximation for capacitance. These two fields taken together satisfy all the boundary conditions of the original region except those at the partition or cut. Fig. 5(C) shows two field configurations which may be superposed with those in (B). When this superposition is made, the resultant configuration is identical with the original, providing that, at the partition, the total potential is continuous and the total of the normal components of flux density is continuous, i.e.,

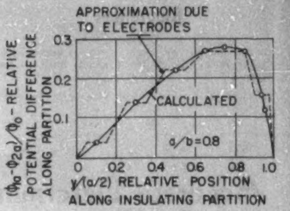

Fig. 6. Difference of field potentials $\phi_{1a}-\phi_{2a}$ at the partition

$$\phi_{1a}+\phi_{1b}=\phi_{2a}+\phi_{2b} \tag{5}$$

$$\frac{\delta\phi_{1a}}{\delta x}+\frac{\delta\phi_{1b}}{\delta x}=\frac{\delta\phi_{2a}}{\delta x}+\frac{\delta\phi_{2b}}{\delta x} \tag{6}$$

at the surface. Because of the insulating partition, the first term on either side of equation 6 is zero, so that

$$\frac{\delta\phi_{1b}}{\delta x}=\frac{\delta\phi_{2b}}{\delta x} \tag{7}$$

at the surface. For convenience, equation 5 is written as

$$\phi_{1b}-\phi_{2b}=-(\phi_{1a}-\phi_{2a}) \tag{8}$$

Inspection of equations 7 and 8 and of Fig. 5(C) will indicate that the boundary conditions required on the compensating field are as follows: 1. Segments of the boundaries corresponding to the conductors in the original problem must be held at zero potential. 2. Segments of the boundaries corresponding to flux lines in the original problem must be flux lines in the corresponding fields. 3. Along the surface of the partition, the normal components of flux densities in the compensating fields must be equal. 4. Along the surface of the partition, the difference of the potentials of the two compensating fields must equal the negative of the difference of the

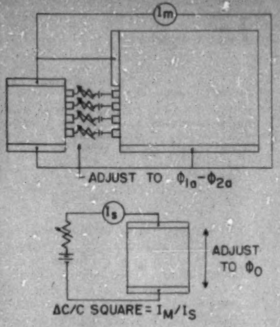

Fig. 7. Electroconducting analog

potentials of the two fields of Fig. 5(B). This difference is calculable. Details of the calculations are shown in reference 3 and typical results given in Fig. 6.

The Analog

With the complete boundary conditions for the compensating fields stipulated, it should be possible to construct the corresponding electroconducting analog. The diagram of such an analog, shown in Fig. 7, is constructed of Teledeltos paper[7] on which boundaries have been placed using silver-conducting paint. All four segments corresponding to the conductors in the original problem are connected together to satisfy the first boundary condition, given in the foregoing. Since current in the analog represents electric flux in the actual field, and since total flux equals total charge at the conductors, the current I_m is proportional to the charge ΔQ on the conductors of the compensating fields of Fig. 5(C). The increment in capacitance due to the compensating fields is thus given by

$$\Delta C=\frac{\Delta Q}{\phi_0}=\frac{\epsilon I_m}{\sigma\phi_0} \tag{9}$$

where σ represents the unit conductance of the electroconducting paper. A convenient means of eliminating σ from consideration is to apply the potential ϕ_0 to a square segment of the paper as indicated in Fig. 7 and read the current I_s. Then

$$\sigma=\frac{I_s}{\phi_0} \tag{10}$$

and the increment in capacitance may be obtained from

$$\frac{\Delta C}{\epsilon}=\frac{I_m}{I_s} \tag{11}$$

The third boundary condition requires that a current flow path be provided between the surfaces corresponding to the partition. For practical reasons, the desired single path is approximated by a finite number of paths in parallel as indicated in Fig. 7. The fourth boundary condition is fulfilled approximately by adjusting the differences in potentials in the current paths according to the curves of Fig. 6, in which figure the stepped curve shows how this potential difference occurs in the analog.

Measurements and Results

To check the accuracy of the method, analog models were constructed for the ratio a/b in Fig. 2, equal to 0.2, 0.4, 0.6, and 0.8 and the ratio w/b approaching infinity. On each model, the boundary potentials were adjusted according to Fig. 6, after selecting a convenient reference potential, ϕ_0. Then the currents I_m and I_s were recorded and the increment in capacitance calculated from equation 11. Results are shown in Table I, in comparison with results of reference 2. For a fair appraisal, per-cent errors are based on the usual fringe capacitance C_f, which, by inspection of equation 4 is given by

$$\frac{C_f}{\epsilon}=\frac{4K(k)}{K(k')}+\frac{\Delta C}{\epsilon} \tag{12}$$

It should be pointed out, however, that when the per-cent errors are expressed relative to the total capacitance, the per-cent error would be less than that given in Table I. It is also significant that these results were obtained with the rather crude 4-step approximation to the potential difference curves of Fig. 6. Had more steps been constructed, even more precise results could be expected. To obtain a comparison of the results of this technique with the more conventional analog method of predicting capacitance-conducting, paper models of the complete field of Fig. 5(A) were constructed, and the capacitance determined by comparing the model resistance with the resistance of a square of conducting paper in the bridge circuit of Fig. 8. The results of this measurement are shown in Table II. Since the conventional method measures total capacitance rather than fringe capacitance, comparisons of total capacitance are made in this table. If fringe capacitances were to be compared, the advantage of the new method would be even more apparent.

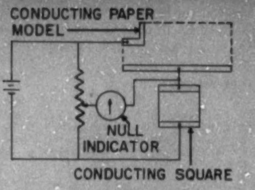

Fig. 8. Conventional analog method for capacitance determination

Conclusions

The usual analytical methods for determining the capacitances associated with 2-dimensional composite regions are generally inadequate to handle any but the simplest of these problems. The usual analog methods are either limited in accuracy, or require extremely precise experimental techniques. The method presented here represents a combination of analytical methods and analog tech-

LATE DISCUSSION

The following discussion was received too late to be included with the paper.

The Logarithmic Diode Counting-Rate Meter and Period Meter

Discussion of paper 57-403 by Bruce B. Barrow, published in Communication and Electronics, September, 1957, pages 421–27.

R. F. Shea (General Electric Company, Schenectady, N. Y.): Mr. Barrow's use of the decilog for growth factor emphasizes the lack of standardization in this field. It must be quite confusing to the neophyte to read of periods in seconds, growth factor in decilogs, doubling time, and decades per minute. I should like to enter a plea here for a concerted effort to adopt one best form, if there be one, and then utilize it. This is not intended as criticism of Mr. Barrow's use of decilog, which I consider quite logical.

In addition to the effects of the various circuit time constants on signal-to-noise ratio and on speed of response, analyzed in the paper, there is a third, very important, function in reactor instrumentation and control: providing a scram or drive-down signal for excessively fast transients (or short periods). The period circuit must be so designed that existence of periods shorter than a prescribed figure will produce this signal if they persist long enough. The duration required must decrease as the period decreases. For example, a drive-down might be required one second after imposition of a 3-second period, but only 100 milliseconds after a 100-millisecond period is initiated. If the integrating time constant is comparable to the differentiating time constant this response time will be lengthened comparatively for fast periods. This consideration usually restricts the integrating time constant to about one tenth of the differentiating time constant. If the response of the period circuit is too sluggish at fast periods the reactor may exceed the danger level during a too rapid start-up.

A similar analysis of the logarithmic-diode smoothing circuit was made in 1953 by H. Hurwitz and E. Clancy of the Knolls Atomic Power Laboratory and reported in internal progress reports. The performance was checked experimentally. The equipment is designed to minimize period overshoot by maximizing K; see equation 27. This is done by making i_0 nearly equal to the minimum detectable current and by minimizing C by the application of negative feedback.

It is interesting to compare Mr. Barrow's analysis with that of Cooke-Yarborough in his 1951 paper,[1] in which the latter describes his system of approximating a wide-range logarithmic characteristic by superposition of a number of saturated characteristics. He also develops an expression for the deviation of the output signal and gives a table showing 21% fluctuation at one pulse per second, 15% at 100 and 4.5% at 10,000. In practice, however, he claims that the standard deviation did not exceed 5% over the 4-decade range. A cursory comparison of these two circuits indicates that both possess the characteristic of incremental resistance inversely proportional to counting rate. From this and other considerations one might conclude that both circuits should have identical transient behavior, if designed to cover the same range with the same response speed. It would be interesting to learn if Mr. Barrow has any information to prove or disprove this.

Finally, in the section "Design of a Low-Level Period Meter," the author conveys the impression that it is impractical to count above 100,000 counts per second, and that resolving times much less than a few microseconds are rare. Nuclear instrumentation has been built which can be used up to 10^6 counts per second, and transistorized equipment is currently under development covering the range of 1 to 10^6 counts per second, with counting loss not exceeding 40%. While, admittedly, circuit design becomes much more difficult, it should be possible to extend this upper limit to possibly ten times this figure. In private communications Cooke-Yarborough has mentioned transistorized scalers counting up to 15 megacycles.

1. An Accurate Logarithmic Counting-Rate Meter Covering a Wide Range, **E. H. Cooke-Yarborough.** *Proceedings*, Institution of Electrical Engineers, London, England, April 1951, p. 98.

Bruce B. Barrow: In his second paragraph Mr. Shea draws attention to what appears to be an error of omission, the failure to discuss the log-diode period meter as a device to initiate scram upon the appearance of excessively fast transients. It is true that first emphasis in my paper is given to the meter as an instrument for aiding in the controlled start-up of reactors. I do not agree, however, that a meter designed according to the principles set forth in the paper, achieving a balance (suitable for a control application) between high noise and rapid transient response, will be inferior as a detector of dangerous transients to a meter with unequal differentiating and filtering time constants. In Fig. 4 are compared different sets of time constants, all of which produce roughly equal performance as noise filters. The combination suggested by Mr. Shea, with one time constant ten times as great as the other (it makes no difference which is the greater), lies somewhere between case II and case III. Except for the first 10% of the transient, case I, with equal time constants, shows faster response. For the first 10% the difference is too small to be shown on the graph.

It is unfortunate that the Hurwitz-Clancy work was not published so that their contribution might be assessed. I infer from Mr. Shea's comments that these authors succeeded in finding the solution of equation 20 for exponential inputs. It appears, however, that they were working on a different problem, presumably at higher flux levels, since in the log-diode counting-rate meter one neither maximizes K nor minimizes C, which is ordinarily an external capacitance of the order of a microfarad.

The standard deviation in counting rate measured by Cooke-Yarborough on his instrument was found to be about 5% at a counting rate of about 90 pulses per second, and he does not report on measurements taken over the 4-decade range of the instrument. His theoretical results on random fluctuations were applied to a meter with shorter time constants than those of his experimental meter, but in any case the random fluctuations in the Cooke-Yarborough meter should decrease with increasing counting rate. In this respect his meter is more sluggish at high counting rates than the log-diode counting-rate meter, and I should hesitate to conclude that both circuits would have identical transient behavior.

Willamette Valley Radio System for the United States Corps of Engineers

C. PEDERSEN
NONMEMBER AIEE

D. J. MARIHART
ASSOCIATE MEMBER AIEE

WINTER FLOODS in the Willamette River Basin in Western Oregon wreak havoc and destruction from frequent flooding of a highly populated and developed valley, 150 miles in length. Congress instructed the United States Corps of Engineers (USCE) to study the problem in the Willamette Valley and to make specific recommendations. As a result the Corps has recommended a system of 16 multiple-purpose reservoirs. These reservoirs were to be located on the major tributaries in the basin and would control a total of 3,200 square miles of the 11,200 square miles in the basin. At the present time five of the recommended reservoirs are in operation, two are under construction, and planning is under way on two more.

The reservoirs were authorized as multipurpose projects with flood control their primary function. Space is reserved in the reservoirs for flood regulation during the rainy season. Following the flood season the same space is filled and provides stored water for irrigation, navigation, power, pollution abatement, and other benefits. Operation of the reservoirs is directed from the District Office; therefore it is essential that reliable communication circuits be maintained at all times between the District Office in Portland and the dams to insure co-ordinated regulation of all reservoirs. This is particularly important during flood periods. Unfortunately, it is during these periods when the usual communication facilities are apt to be out of service, as most of the dams are serviced by facilities which utilize overhead wires for at least part of their communication circuit. Overhead wires are particularly vulnerable during periods of intense storms. This concern lead to the initiation in 1954 of a radio communication system for the Willamette Valley. By providing an alternate means of contacting the dams there would be less possibility of a complete communications breakdown during a crucial period. Ineffective co-ordination of a system of flood-control reservoirs, which could occur if communications failed, could result in failure to provide adequate control, or possibily even in aggravated damages. Elimination of such a possibility clearly justified the construction of an alternate means of contacting the dams during emergency situations. Commercial telephone service between the District Office in Portland and the dams was retained as an important component part in the communication facilities between the District Office and the flood-control dams.

General System Plan

Original planning for a radio communication system linking the District Office in Portland with the existing flood-control dams, considered the use of low-frequency radio equipment. This type of equipment does not require line-of-sight transmission, and there is no need for repeater stations. However, it does present other problems that could reduce the reliability of such a system. These unfavorable characteristics are skip, fading and a high noise level.

After serious consulation with experienced radio engineers it was decided to install very high-frequency radio equipment. This immediately raised the question of repeater stations, which are expensive to construct and maintain. In the process of investigating these aspects of the radio communication system, the idea of utilizing microwave for the backbone of this radio system was discussed with Bonneville Power Administration (BPA). It was agreed that one audio channel of their microwave system between Portland and Coburg would be available to the Corps of Engineers to facilitate a wireless communication system between the District Office in Portland and the existing flood-control dams in the Willamette Valley. This eliminated the need for constructing repeater stations.

Four of the existing five dams in Willamette Valley are within 35 miles of

Fig. 2. Block diagram of radio system: Willamette River Basin, Oregon

the Coburg microwave station and the fifth, Detroit Dam, is within 30 miles of the Prospect Hill microwave station. The communication between the District Office and the dams was planned as vhf (very high frequency) between the District Office and the Interior Building in Portland, microwave from the Interior Building to the respective microwave stations, and then vhf from the microwave stations to the flood control dams. The system layout is shown in Fig. 1. Microwave repeater stations are ideal locations for vhf land stations because of their high elevation and the existence of housing, antenna tower, and power facilities. The basic system plan resolved itself as follows:

1. A very low power (5-watt) vhf point-to-point radio link between the USCE District Office and the Interior Building in Portland where the BPA terminates all of its main microwave systems, including the Portland–Alvey system.

2. Full duplex, 50-watt vhf land stations at Prospect Hill and Coburg Microwave repeater stations.

3. The two vhf land stations would be linked to the flood-control dams by means of half duplex, push-to-talk, 50-watt vhf fixed stations at each of the dams. The vhf station at Prospect Hill would serve Detroit Dam and the Coburg vhf station would serve Fern Ridge, Cottage Grove, Dorena, and Lookout Point Dam.

A block diagram of the system as proposed is shown in Fig. 2.

Field Surveys

Vhf field strengths between the USCE dams and repeater stations were established using a jeep with a 25 watt vhf mobile set connected to a 36-foot portable mast and quarter wave whip antenna at the Microwave repeater stations. In most instances the topography between the dams and repeater stations prevented direct line-of-sight communication. A panel delivery sedan equipped with a 25-watt vhf mobile set was used at each of the dam sites to check received vhf signal strength from the microwave stations. The vhf receivers were calibrated with a Measurements Corporation Model *76FM* r-f (radio-frequency) signal generator. (See portable vhf test equipment, Fig. 3.)

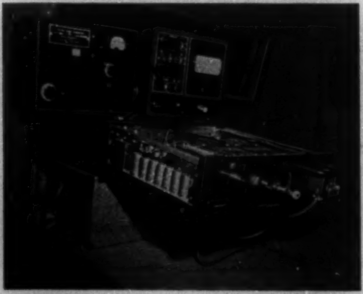

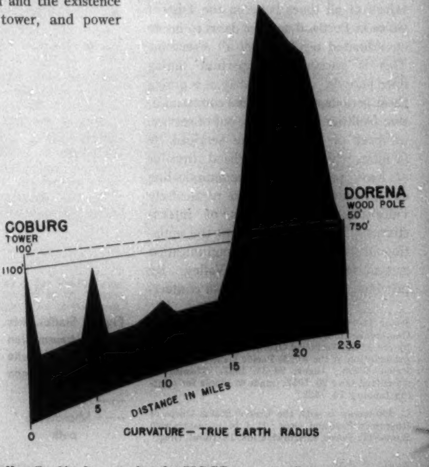

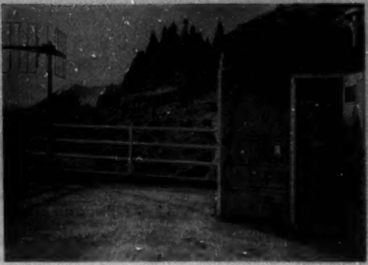

Fig. 5 (left). View of Dorena Dam installation. Gage house door open showing vhf equipment rack and antenna on pipe

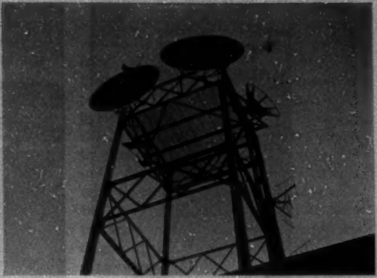

Fig. 7 (right). Closeup view of USCE vhf and BPA microwave parabolic antennas on Interior Building tower

Of the five vhf links to the dams, only the one to Fern Ridge Dam was a line-of-sight path. The other four paths were similar to the Dorena–Coburg path shown on the profile map of Fig. 4. Since the reception at these sites was due to reflected waves, a careful check was made to determine the values of nulls and maximums in the standing wave pattern. The minimum signal strength recorded for any of the Links was 2 microvolts at Cottage Grove. A typical vhf receiver input sensitivity is 0.6 microvolt for 20 db (decibels) quieting. The preliminary surveys proved that the communication network contemplated by the USCE was entirely feasible from an engineering standpoint. In general, it was decided to employ transmitters having a minimum output power of 50 watts and high gain directional antennas at all stations. The antennas at the microwave stations would be semidirectional, having a cardioid radiation pattern, to provide sufficient beam width to cover the geographical spacing of the damsites. It was evident that these factors together with the higher antenna elevations possible in the final installations, would provide considerable improvement over the survey data and would result in an ultimate communication system having a high degree of reliability.

The Willamette Basin communication system was authorized on the basis of the preliminary survey data early in October 1954. Shortly thereafter a joint field survey was made by USCE and BPA engineering personnel to Lookout Point, Dorena, Cottage Grove, Fern Ridge, and Detroit Dams for the purpose of determining equipment mounting locations, power and communication circuit routings. The following plan as shown in Fig. 2 was evolved on the basis of this survey:

Lookout Point Dam. Space for the radio equipment rack was assigned in the small communications room which was directly north of the control room. A 117-volt a-c clock bus power outlet was available there to supply continuous power to the radio equipment even in the event of a station service outage. The antenna was to be mounted on top of the powerhouse.

Cottage Grove Dam. Space for the radio equipment rack was designated near a desk in the office building. The antenna was to be mounted on a 50-foot wood pole 2 feet from the south end of the office building.

Fig. 6. Over-all view of Interior Building showing vhf antennas on tower

Dorena Dam. Space for the radio equipment was reserved in the north end of the reservoir gagehouse on top of the east end of the dam. A combination underground cable and overhead telephone line was planned from the adit house in the dam to the Office Building and resident engineer's house approximately one-half mile distant; see Fig. 5 for a picture of the Dorena Dam installation.

Fern Ridge Dam. Space for the radio equipment rack was assigned in the east end of the office space in the Operations Building. The antenna location was selected on a power service entrance pole near the office. An open wire telephone line was required for an extension telephone in the operator's residence 400 feet away.

Detroit Dam. Space for the radio equipment rack was selected in a small room adjacent to the elevator shaft, one floor above the waiting room near the north end of the dam. The waiting room is on a level with the top of the dam. The antenna was scheduled for an unimposing location above the northwest corner of the elevator shaft structure.

System Design

No special buildings were needed for this system. The system was laid out to use existing buildings in all cases. At the dam sites the equipment was located either in the dam structure itself or in office buildings nearby. At the microwave stations, the vhf repeater equipment was located in the same room with the microwave equipment. The microwave buildings are concrete structures, approximately 27 feet square and 11 feet high; see Figs. 5, 6, and 7 for pictures of the

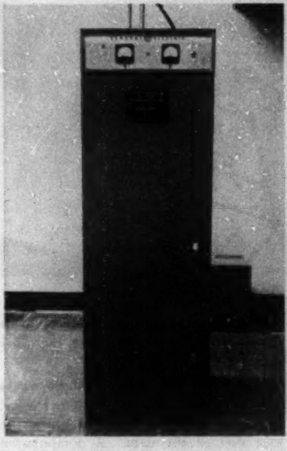

Fig. 8. Front view of vhf base station with cabinet door closed

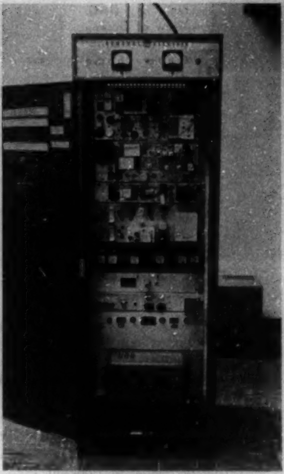

Fig. 9. Front view of vhf base station with cabinet door open

Fig. 10. Vhf base station meter panel

the final installations at Dorena Dam and the Interior Building, respectively.

Only two antenna poles had to be set for the system. In all other cases either existing towers or wall supports were used. The towers at the microwave stations are of the self-supported, lightweight, steel transmission type with top mounted platform. The vhf antennas were located on the sides of these towers.

Equipment Specifications

"Turnkey" type specifications were written requiring the contractor to prepare the necessary detailed design for system components, supply all of the material, install the equipment and energize and test the completed communication system. Fulfillment of the contract required that a satisfactorily operating communication system be turned over to the Corps of Engineers. Land-Air Incorporated of Chicago, Illinois, the successful bidder, supplied the following basic system in accordance with specifications.

Vhf Radio Installation

General Electric 50-watt base station vhf radio equipment was provided for each of the nine locations, including the point-to-point link in Portland between the BPA microwave terminal in the Interior Building and the District Office in the Pittock Block Building; see Figs. 8, 9 and 10 for pictures of the equipment. The vhf base station equipment at the microwave stations and at the Pittock Block Building were equipped with blowers for continuous full duplex operation while the rest of the vhf radio racks at the dam sites were provided without blowers for intermittent, push-to-talk, half duplex operation. It should be noted that since three of the vhf stations, Fern Ridge, Interior Building, and Pittock Block, had line-of-sight paths, the vhf transmitters are operated at a reduced power output of five watts. The six other stations are operated at about 80% peak r-f power output.

Special Features

The vhf system incorporated the following unique features:

1. Base station equipment at the microwave stations and at the Pittock Block Building operate full duplex continuously, using transmit frequency of 163.425 megacycles (mc) and receive frequency of 167.175 mc. The Interior Building vhf station operates on 167.175 mc transmit and 163.425 mc receive. Transmitting and receiving antennas are spaced vertically on a pipe mounting. With this spacing and 4 mc frequency separation, cavities are not required to prevent receiver desensitization.

2. Any station in the system may selectively call any other station by dialing a standard telephone set. This dial, through a relay panel, keys a 3,000 cps (cycles per second) tone generator at the dial rate of 10 impulses per second. The signal is transmitted through the system and is received at each one of the vhf stations on a 3,000 cps tone decoder which operates a stepping switch in accordance with the dial pulses for ringing the called station. The selectors at each station operate every time any call is placed. Only the selected one will operate the telephone ringer, the others will be automatically reset after a 10 second delay. In addition to the selective call at each station, there is a conference call number, 9-0, which will cause all station phones to ring. This, of course, is used for emergency purposes only. The numbers used in this system are relatively simple, utilizing a series stepping arrangement, e.g., 9-1, 9-2, 3, etc. Of course the vhf sets at the dam station, being push-to-talk, have to be turned on during the transmission of the dial pulses. When a connection has been made, any third party may break in at any time in case of emergency. The radio sets at the Pittock Block operate full duplex, hence, there is no push button on the telephone hand set. The bridging network necessary to accomplish the above functions at the Prospect Hill repeater station is shown in Fig. 11. An initial attempt to parallel three hybrids was not successful.

3. A ringback feature is provided at the vhf repeater stations so that a station at the dam may dial the vhf repeater station number; e.g., 9-2, for Coburg and receive an interrupted ringback tone of 60 cycles. Reception of the ringback indicates to the calling party that the vhf link is operating.

4. Another unique feature of this system is that it is designed for a future reception of hydrologic data through telemeter signals of both repeater stations. When these signals come in, they will be in the upper end of the audio range between 2,800 and 3,200 cps.

Components of System Cost

The following percentages, represent the breakdown of costs on this particular job, and give an indication of what may be expected in locations of this nature, for systems of the type outlined:

Item	Per Cent of Total
Field surveys	1.5
Engineering	6.5
Vhf radio equipment (including installation labor cost)	85.5
Test and energization	6.5

In this particular system the cost of land, housing, site development, towers, emergency power, commercial power and roads was negligible since all of these were existing. This, of course, contributed to a very economical over-all system cost.

System Installation and Operation

The tests revealed the following system quality:

Test No. 1. Stability Versus Line Voltage. The Interior Building vhf Station was selected to be spot checked because of the relative ease in varying the voltage ±5% from 117 volts alternating current. The General Electric vhf equipment *r-f* stability was ±0.0003% which is within the specification requirement of ±0.0025%. The audio level stability was better than −2.0 db which is very good.

Test No. 2. Audio Level Settings and Dial Check. The audio level settings based on a 1,000 cps continuous tone were +6.5 dbm at the vhf receiver output. This is 14.5 db above the specifications minimum requirement of −8.0 dbm. All of the stations were dialed at least three times from every other station. Most stations responded on all three calls, some stations responded on two out of three attempts.

Test No. 3. Noise. The average F1A weighted signal to noise ratio of all links tested was 34.9 db with a maximum for one link of 45.8 db and a minimum of 28.0 db. This compared to a specification requirement of 40.0 db; however, it was felt that 40.0 db was too stringent for a vhf system and that a more practical value would be 30 db. The average of 34.9 was considered acceptable.

Test No. 4. Audio Channel Frequency Response. The average deviation between 300 cps and 3,000 cps for all links tested was ±4.4 db which was only 1.4 db above the specification requirement of ±3.0 db. This was considered as a minor exception to the specification and was acceptable.

Test No. 5. Harmonic Distortion. The average harmonic distortion for all links tested was only 5.7% which was well within the specification requirement of 10.0% maximum.

Test No. 6. Vhf Receiver Sensitivity. The received signal strength for each station was greater than the minimum specification requirement of 6 microvolts. Since the maximum receiver sensitivity is 0.6 microvolts for 20 db quieting, a minimum fade margin of 20 db was assured for each station.

The average r-f transmitted power for all stations was 59.6 watts which was well above the specification minimum requirement of 50.0 watts. For normal operation it was recommended that each station be operated at the lowest practical power, e.g., 40 watts, in order to extend tube life and minimize emergency maintenance calls.

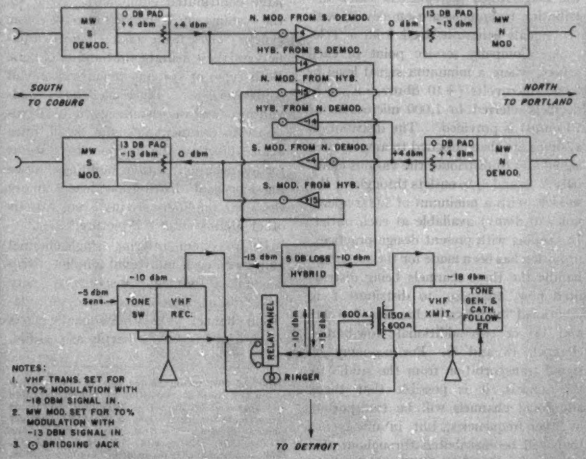

Fig. 11. Block diagram of bridging network at Prospect Hill

Maintenance Logs During Test Period. A total of 18 separate problems were worked on over the two month period from Aug. 27, 1956 to Oct. 27, 1956. Of these 18, only seven were maintenance problems which ranged from weak tubes to blown fuses. The remaining 11 were of the "debugging" type which were solved by permanent modifications being made to the equipment. Considering that nine separate vhf equipment racks comprise the system, only seven maintenance problems over a two month period indicated that good, reliable service can be expected from the system with a normal routine maintenance program.

During the initial phases of putting the equipment into operation and subsequent testing, problems presented themselves as is the case in most systems of this type. These were overcome in the following manner:

1. One of the first problems which had to be solved was the strange behavior of the Coburg to Dorena Dam vhf link. This path was non-line-of-sight as indicated by the beam path profile shown in Fig. 4. The Dorena antenna was first mounted on the north side of the gagehouse on top of the dam structure and oriented for maximum received vhf signal strength. After a month of operation, it was noticed that the signal strength was varying from an unusable minimum to maximum although there was no noticeable movement in the antenna structure. The change in signal strength was finally attributed to the fluctuation in tailwater, which was immediately below the location of the antenna. The tailwater had been reflecting the vhf signal to the antenna, causing extreme fading. The solution to this problem was to move the antenna location ten feet further north and 15 feet higher in elevation where the effect of the reflected signal was minimized.[1,2]

2. The second problem was the one of overmodulation on the microwave channel due to excessive signal level input from the vhf receiver at the repeater station. Trouble was experienced with the station at Prospect Hill because a spurious harmonic from a neigboring vhf station was getting into the USCE vhf receiver and causing the squelch to open. This allowed excessive noise levels of 10 to 12 db above normal at the microwave modulator inputs.

In the original design the microwave input level was to be determined solely by the vhf receiver level output control. This made it relatively easy to overmodulate the microwave since the output control was a continuously variable type of potentiometer. The solution to this problem was to insert 13 db pads on the microwave modulator input circuit. This requires the vhf receiver output level to be 0 dbm and makes it more difficult for an inadvertent high level potentiometer setting on the audio output level of the vhf receiver.

3. The third problem was one of getting the 3,000 cycle decoders to operate properly at the vhf repeater station. A dial repeat relay was added at Coburg to boost the level

of the 3,000 cps dial pulses for proper operation of the dial selectors at Prospect Hill and the Interior Building. Without the dial repeat the tone level was −10 dbm which required the repeater station tone switch sensitivities to be set at maximum and thus make them susceptible to sharp noise transients on the microwave system. The dials at all push-to-talk stations had to be slowed down from 10 impulses per second to 6 impulses per second to permit the Coburg repeat relay to follow the dial pulses accurately. However, trouble was then experienced with the dial repeat relay because of pulse distortion. The final solution was to turn off the selective calling feature at the vhf repeater stations at all times except when maintenance personnel were at these stations. The original 3,000 cps tone from the push-to-talk vhf station is now transmitted directly over the microwave channel to the Interior Building where it is amplified and then transmitted over the vhf link to the Pittock Block.

4. The fourth problem was one of operation wherein the operators who had little or no previous experience with VHF radio equipment tended to talk too loudly into the telephone handsets. This resulted in audio distortion because of clipping by the modulator deviation limiters. Ten db *T* pads were inserted on the vhf transmitter audio input circuit.

5. It was found that the transmitters would drift on power output when operated at their peak efficiency of 60 watts output over an extended period. It was recommended that the vhf transmitter output power be limited to 40 watts at all stations to prevent this trouble from recurring. More efficient blowers may be the permanent solution in a case where it is essential to operate the sets at their maximum power output.

Over-all the system has been working very well for the past year. Two men are used to maintain the entire system of nine stations. These men are located in Portland and have other duties in addition to the Willamette Valley Radio System maintenance. They go out on routine maintenance calls to the stations about once a month. The stability of the tone generators and decoders is very good. Many of the stations have been in operation for over a year with hardly any noticeable frequency drift. This type of system is highly recommended for similar flood control applications.

Television Systems for In-School Teaching

MAX H. KRAUS
ASSOCIATE MEMBER AIEE

THE Teaching-by-Television Experiment now being conducted in Hagerstown, Maryland, under the joint auspices of Electronic Industries Association, the Fund for the Advancement of Education, and the Washington County School District has been described in considerable detail.[1] The early success of this 5-year experiment, which now encompasses 8 schools, with 6,000 pupils, and which eventually will cover all of Washington County, with its 48 schools and 18,000 pupils, is being watched carefully by all those concerned with improving our educational techniques.[2] The plant provided by the Chesapeake and Potomac Bell Telephone Company to link the studio with the schools and the details of the well-equipped studio have been the subjects of separate discussions. This paper will describe the "in-school" or "receiving" portion of the Hagerstown facilities and also will consider possibilities for the future.

System Design

The Television Distribution Systems used in Hagerstown are of the type usually found in schools where signals are received by off-the-air pickup of broadcast stations and distributed from the pickup point to the various classrooms. In the case of the Hagerstown systems, the same distribution techniques are employed, with the signals being obtained from a Telephone Company service point in each school, where a minimum signal level of 3,000 microvolts (+10 dbmv, i.e., +10 decibels referred to 1,000 microvolts at 75 ohms) is provided. The distribution systems are then designed to amplify this signal and to distribute the various channels (2, 4, and 6) to outlets throughout the schools, with a minimum of 1,000 microvolts (0 dbmv) available at each outlet. In keeping with present design practices, provision has been made for the system to handle the three channels being distributed now, but, also, to distribute four additional "high-band" channels (7, 9, 11, and 13) or two additional "low-band" channels (3 and 5). For economy of signal transportation from the studio to the schools, it is possible that these additional channels will be transported at other frequencies; but, in any event, they will be distributed throughout the school using regularly assigned channels so that they can be received on conventional receivers. In this connection, it is recommended that the wiring and other permanent parts of all school television distribution systems be designed to handle all channels (2–13) so that no matter what channels are added, changes will be necessary at only the "head-end."

As might be imagined, several types of distribution systems and master amplifiers can be used, depending on the size of the building in question. In the case of the Washington County Systems, this has been somewhat complicated by the fact that a number of different manufacturers have contributed equipment. Even so, the systems can be divided into two basic types: Those using single-channel amplifiers and those using broad-band amplifiers. Both types of systems are in widespread commercial use. Since each has its advantages and disadvantages, it is appropriate to comment in some detail, once again directing the analysis to systems for distribution within buildings—since for long-haul distribution where many cascaded amplifiers are involved, various other factors enter the picture.[3]

In a system utilizing single-channel amplifiers, each individual amplifier strip has a flat frequency response (usually ±1/2 db) across a 6 mc (megacycle) television channel. On either edge the skirts are designed to fall as sharply as possible.

Paper 57-669, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted April 16, 1957; made available for printing January 7, 1958.

MAX H. KRAUS is with the Jerrold Electronics Corporation, Philadelphia, Pa.

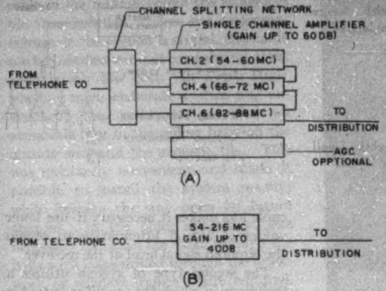

Fig. 1. Amplifier systems

A—Single channel
B—Broad band

The input signal to the master amplifier may be obtained from a common signal source, as is done in Hagerstown (Fig. 1), or each amplifier may be fed from a separate antenna or camera. In either case, the system has the advantage of giving the installer control over the amplification and resultant signal level of each channel, independent of the others. Automatic gain control techniques frequently are applied, and a very flexible system results. Then, too, the relatively narrow amplifier bandwidth makes it possible to obtain higher gains for each stage of amplification than in a broad-band amplifier. Finally, it is possible to obtain both a significantly lower input noise figure and a higher output voltage, since, regarding the latter point, the allowable output voltage in a single-channel amplifier is limited by sync clipping, while in a broad-band multi-channel amplifier, intermodulation between channels gives trouble at a much lower output voltage. Using conventional receiving tubes, it is not unusual to obtain 1.5 volts rms (63 dbmv) per channel from a single-channel amplifier, while limiting the output of a broad-band amplifier to 0.3 volts rms (+50 dbmv). This latter advantage is particularly important in large buildings, such as the new Hagerstown South High School, where a single master amplifier (Fig. 2) is capable of feeding several hundred connection points, even though some eventually may be located over 1,000 feet away from the amplifier.

The broad-band amplifier is at its best in small systems where inidividual channel control and high-output voltage are less important; see Fig. 3. Several types of broad-band amplifiers are available, including chain amplifiers having bandwidths up to several hundred megacycles and others in which two broad-band sections—one covering Channels 2 through 6 (54–88 mc) and another, Channels 7 through 13 (174–216 mc)—are combined in a single unit. In systems of this type (Fig. 1), depending on the type of broad-band circuitry used, the power consumption is reduced, as well as the initial cost and eventual operating costs. Most television distribution system manufacturers have both types of systems available, so that the most desirable one may be chosen for a particular installation.

Before leaving the subject of system design, it should be mentioned that two types of system layouts are possible, with the choice once again determined by the size of the system. Fig. 4 shows a system in which each output of the amplifier is "split" by a resistive (6 db loss) or reactive (3 db loss) splitter to form two trunk lines. From these trunk lines, riser or feeder cables reach into the various areas of the building, with receiver isolation tap-off units inserted at various points to provide lines for the actual set connection. Each set connection point is provided with a matching transformer to im-

pedance match the 300-ohm receiver to the 75-ohm distribution system. All trunk and feeder lines are terminated by 75-ohm terminating resistors, and every effort is made to provide a matched 75-ohm system throughout. Even the receiver isolation tap-off units are compensated to prevent standing waves and resulting ghosts. In such a system, the tap-off unit provides a minimum isolation of approximately 10 db between the receiver and the feeder line, thus preventing the sets from interacting with the system or each other. The feed-through loss through such a tap-off (loss in the direction of the feeder) is low, ranging from 1.5 db for a unit with a 7 db tap-off attenuation (at Channel 13) to only 0.1 db for a 32.5 unit (at Channel 2). The tap-off units themselves are usually predominately capacitive, so that their tap-off attenuation is less for higher frequency signals than for the lower ones. This compensates for the inherently higher high-frequency loss of the cable and insures a more uniform signal input to each receiver. Fig. 4 shows typical signal levels for a section of a system, while Table I shows the specification for a series of receiver isolation units. In this case, the units with the higher tap-off attenuation are used closer to the amplifiers, while the lower value units are used at the extremities of the system, where the cable loss makes it necessary to use lower values of tap-off attenuation to obtain the required signal level at the reciever.

The second type of system utilizes a technique in which the amplifier output is "split" into four or eight lines, which are then connected directly to the receivers without using receiver tap-off units. This makes it possible to reduce the loss between the amplifier and the ultimate receiver, with a resulting decrease in necessary amplifier voltage; but as shown in Fig. 5, this technique is limited to smaller systems having short cable runs and has the disadvantage that it is difficult to expand the system, while in the former case, additional tap-offs can be added along any feeder cable without disturbing the over-all system in any way.

System Installation

As far as the physical installation of the system is concerned, several approaches are used. In new construction, conduit is generally provided between the chosen amplifier location and the various room outlets. Ideally, the system should be engineered at the time that the building is designed, so that outlets, pull boxes, etc., are located at appropriate points for the maximum economy in time and material. In those cases where this is not possible, a simple riser system, following the general outlines of Fig. 4 and utilizing 3/4-inch or 1-inch conduit throughout, will frequently suffice and will save many hundreds of dollars in future installation costs.

For existing buildings, it frequently is possible to combine the television distribution system wiring with existing sound systems or any one of the various signal services which one finds in a modern school. Where conduit is not available, air shafts or heating ducts frequently are employed or, as a final resort, the cables may be left exposed in the room with protective wire mold used where desired. The Hagerstown School System, being composed of both ultramodern schools and older buildings, utilizes a combination of all of these approaches. In the new Pangborn Elementary School, for example, it was possible to install the

cable in the ceilings before the acoustical tile was installed. Since the maximum voltage in the system is trivial, this cable can be installed without conduit and, thus, at relatively low cost. In South High, where a more elaborate system was envisioned, the architects provided an accessible tray in the ceiling between the outside wall and the acoustic tile. This was extremely convenient and made it possible to install the system readily, while keeping the way open for future changes. In the older schools, it was necessary to install the cable through the halls with holes drilled through the brickwork or window frames where required. Even here, installation can be accomplished speedily using present-day installation techniques.

As can be imagined, the actual direction of the feeder or riser cables is usually in the long dimension of the building. In other words, in multi-story buildings, the rooms are connected from floor to floor, with all rooms in a vertical line being served from the same feeder cable. The modern trend of low, spread-out schools has changed this technique to one in which feeder cable running the length of a hall is used to provide service to the rooms on either side.

Classroom Considerations

Having provided the signals with a path throughout the building, we arrive at the classroom itself. Anyone who has been privileged to watch a class eagerly responding to television teaching is at once struck with the importance of the viewing atmosphere; see Fig. 6. It may be trite to say that the atmosphere must be conducive to learning, but one cannot underestimate the importance of the receiver, its placement, the room lighting, etc.

In a field where hard-and-fast rules have yet to be devised, it still may be of value to others to state some of the "rules of thumb" used in equipping the viewing rooms in Hagerstown. First, it was decided that in the elementary grades, where the students spend most of their time with one teacher in a particular room, all classrooms should be television-equipped so that the students could view their television teaching in familiar surroundings. To provide the desired intimacy between the pupil and the receiver, it was decided to provide sets in the ratio of one set for every 15 students, with a minimum of two sets in each room. According to the standards set by some authorities, this is an unnecessarily generous figure; but since Hagerstown was

Fig. 6 (above). Elementary class watching television

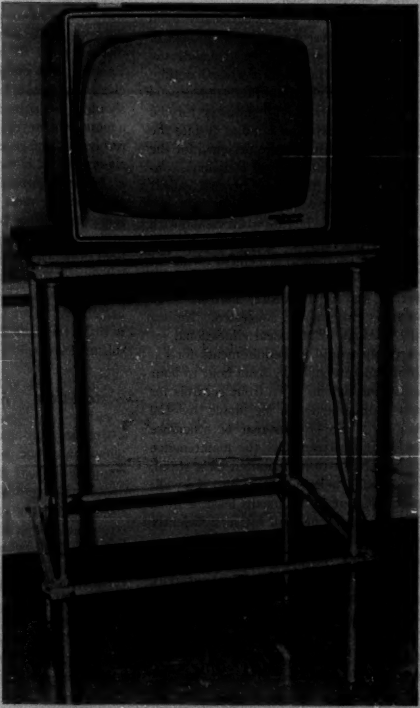

Fig. 7 (right). Television set on stand

designed as a general experiment in learning, it was decided not to attempt to reduce coverage, as might be done in a future test concerned with determining the minimum equipment necessary. In the upper grades, the fact that students are accustomed to moving made it possible in some instances to effect economies by selecting only a few larger television rooms, where four sets have been used. In this latter case, it has been proposed that a study be made to determine the relative learning of students viewing in large groups, as opposed to normal-sized classes. Although this matter must be settled by the educators, rather than by the engineers, it certainly would seem that in terms of flexibility and ability to handle an entire school at times of special-interest programs, the idea of equipping every room has much to commend it. Certainly, even in those cases where, costwise, it is impossible to provide television receivers in every room, the television distribution system should be installed throughout the building, so that reception can be provided easily when required by using moveable sets.

The design of an educationally ideal television reciver could be the subject of an entire paper; but, once again, the experience in Hagerstown is worth noting. A variety of styles and brands of receivers have been provided by industry for the Hagerstown experiment; and despite the fact that almost all were designed for the highly competitive, cost-conscious consumer market, they have given excellent service. Most receivers are 21-inch and give an excellent picture when viewed with normal room illumination if suitable attention is given to placement of the set and to proper blinds or drapes. For the record, and for the future, there are some changes that can be suggested. Among the features of the ideal educational set certainly would be requirements for extreme picture stability from hour to hour and from day to day; front controls for any adjustments to be made by the teacher; tamperproof rear or otherwise hidden adjustments for the maintenance man; ability to be mounted on a stand, on a wall bracket, or built into the wall; and last, but by no means least, a front loud-speaker powered by a sufficiently powerful, high-quality sound system to reach all of the pupils with top-quality sound. In this latter case, a set certainly should have the ability to provide at least 5 watts of undistorted sound.

The television set stand used in Hagerstown was designed by members of the school staff and deserves special mention. As shown in Fig. 7, it combines the features of ease of construction, minimum cost, and portability with extreme ruggedness and functional stability. Three sizes have been used, with heights of 38, 41, and 44 inches. The lower ones have been particularly useful in the lower grades, where, wherever possible, the sets have been placed along the long wall of the room. The lower elevation is particularly desirable when the lesson combines both television viewing and student desk work, since the less amount of head movement between the student's normal writing position and his television viewing position, the better his attention and the less his fatigue when changing from one activity to the other. These particular stands do not provide a downward "tilt" to the receiver, but are easily adapted should such be desired.

As mentioned before, considerable thought has been given to room lighting and to the placement of the television receivers. Ideally, the sets should be placed so that the students can view them without changing from their normal seating pattern and position; furthermore, it is desirable to place the sets along the long wall of a classroom, so that the distance between the television set and the most distant pupil is kept to a minimum. Finally, light coming from outside the classroom should fall over the pupil's left shoulder in the traditional fashion and in a manner to prevent glare on the television receiver. Unfortunately, in many actual classrooms, it is not possible to combine all of the desirable features, so that many compromises must be worked out. In some cases, it has been found desirable to utilize window drapes to block incident light from disturbing the viewing. Room lighting is then supplied by the regular room fixtures to the desired degree. Unlike movie viewing, it is not necessary to make the room light-tight, with the resulting decrease in air circulation, etc.

System Cost

Certainly no analysis of the in-school television system in Hagerstown would be complete without mention of cost. The distribution systems themselves vary in complexity, from those serving a few rooms to the potentially elaborate system in South High School. In other areas of the country, the number of channels, the type of building construction, and local factors will affect the individual costs. In general, however, experience has shown that a complete television distribution system for a school of from 10 to 60 rooms can be provided at a cost ranging from $25 to $50 a room. This figure includes all labor and material for the system, except for the cost of any conduit provided as part of the original building. The cost of the television set, etc., must be added to this system cost. The stand for the television set adds approximately $20 to $25, while a 21-inch receiver can be purchased for between $125 and $150. Based on present labor and material costs, therefore, it is safe to allow between $175 and $200 as the total cost for each installed television-equipped room.

Future Possibilities

Thus, in Hagerstown, we find television systems that are providing low-cost, reliable television viewing to some 6,000 pupils, with planned expansion to over 18,000 students. Already the over-all program has proven itself to have a tremendous potential in improving the very basis of American education. At such a time, it seems appropriate to point out that while the Hagerstown facilities already have attained a high degree of education acceptance, they have actually been in use for only a short time and that there are many technical features which remain to be tried. Many other experiments have been conducted,[4,5] and many groups of statistics have been collected. Although it would be both impossible and pointless for the Hagerstown work to duplicate these other studies, there are some areas which deserve attention. To date, for example, only conventional-size television screens have been used in Hagerstown. Certainly, an experiment with as broad a base as that being carried on in Hagerstown deserves the chance to try large-screen projection as an educational tool. Recently developed equipment would seem to make it possible to utilize such equipment effectively for auditoriums and other large assembly areas.

System-wise, to date, all of the teaching in Hagerstown has been done from a single location. Certainly there are teaching situations where the reduction in the number of pupils being taught will be desirable and where it will be possible to introduce actual voice communication between students in viewing rooms and the teacher. It is possible that this approach may be more applicable to the college atmosphere than to high school and elementary education; nevertheless, it is an approach that is technically possible and is being explored elsewhere.

In a similar vein, the system now installed in South High School has the ability to provide "Two-Way" television[6,7] so that if, at sometime in the future, it becomes desirable to originate programs from the various classrooms, laboratories, or shops of this high school to be viewed at other locations in the school system, the facilities are already available.

Expanding on this concept, it is possible to think of the coaxial cables as broad streets, over which many types of programs and signals can be carried, so that by introducing tone-control equipment in other portions of the radio-frequency sprectrum, it will be possible to give individual instructors the use of control channels to direct experiments or facilities at other locations, which, by virtue of size or distance, may be best integrated into the teaching program by way of a television link.

Finally, in this atmosphere of technical exploration, one may challenge the basic television standards themselves. Certainly, in a completely closed-circuit system, there is no technical or legal necessity for using conventional broadcast standards for picture transmission. There may be instances where, because of requirements for greater details, it will be desirable to use wide-band systems that provide additional definition. On the other hand, possible economies of equipment can be achieved by using narrow-band systems with high-persistence screens for the display of charts and supplementary material where motion is not required. All of these techniques are now technically possible through the use of equipment already available; and while some are being evaluated by educators, many others remain untouched.

Conclusions

In summary, I should like to express my appreciation to the electronics industry, the Fund for the Advancement of Education, the Chesapeake and Potomac Bell Telephone Company, and the Washington County School System, who have made the Hagerstown experiment possible and who have assisted in preparing this paper, and, at the same time, to urge that additional groups of educators and engineers continue to work together to further solidify this marriage of electronics and education.

Transient Response of Impulse Voltage Dividers

F. A. FISHER
ASSOCIATE MEMBER AIEE

WITH modern test instruments it is possible to measure the transient response of an impulse-voltage-divider system directly and with good accuracy. The response to a step function, a wave which rises to its steady-state amplitude instantaneously, is particularly easy to determine. This is fortunate since a good approach to understanding the transient response of a complicated system is through study of the step response. The purpose of this paper is threefold: to explain the significance of the step response, to relate the step response to the over-all transient response of the system, and to relate the crest accuracy and step response of a divider system by means of simple accuracy curves. Certain methods which may sometimes be used to improve the response of practical impulse voltage dividers will also be discussed.

Sources of Error in Impulse Voltage Dividers

Most impulse voltage dividers presently in use fall into one of four categories: resistance dividers, shielded or unshielded, capacitance dividers, and mixed dividers. Although this paper is primarily concerned with resistance dividers, much of the material applies equally well to capacitance dividers.

Fig. 1, a schematic diagram of a common resistance-divider system, shows the elements that affect the transient response the most. While such a diagram is well known and the elements easily recognizable, several tacit assumptions are often made when analyzing such a system. First, attention is frequently focussed on only the high-voltage arm neglecting the effect of connecting leads and the low-voltage arm. Second, all the error is assumed to be caused by uncompensated charging currents through the stray ground capacitance of the high-voltage arm. The effects of inductance and through capacitance are usually neglected since they make it difficult to solve the differential equations describing the high-voltage arm.[1] Third, it is assumed that the low-voltage arm should be a pure ohmic resistor, or perhaps that it should have the same L, R, and C characteristics as the high-voltage arm.

Since the purpose of the divider is to produce a replica at the oscilloscope of the voltage being measured, and since each of the elements may cause errors, the

Paper 58-37, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 14, 1957; made available for printing November 4, 1957.

F. A. Fisher is with the General Electric Company, Pittsfield, Mass.

The author wishes to acknowledge the guidance and valuable suggestions of J. H. Hagenguth, A. F. Rohlfs, and J. S. Kresge.

term "divider" in this paper will refer to the entire measuring system including the connecting leads. The primary attention will be given to the performance of the over-all system.

Relationships Between the Step Response and the General Transient Response

The over-all response of a system may be specified in several ways, any one of which is sufficient to describe the complete transient and steady-state response of the system. The response may be specified in terms of the steady-state frequency and phase-shift characteristics,[2,3,4] in terms of the response to an impulse (a wave of infinite amplitude and enclosing a net area of unity), or in terms of the step function response.[5,6] Of the three, the response to a step appears the simplest to relate to the over-all accuracy of the system.

The step response is related to the general transient response by the superposition integral (also called the convolution or Duhamel's integral),

$$h(t)=\int_0^\infty f(\tau)\frac{d}{dt}[\phi(t-\tau)]d\tau \qquad (1)$$

where

$h(t)$ = response to the input
$f(\tau)$ = arbitrary input
$\phi(\tau)$ = response of the system to a step function
$\phi(t-\tau)=\phi(\tau)$, but reversed left to right and shifted to the right by an amount t

An alternative form of equation 1 is

$$h(t)=\int_0^\infty \frac{d}{dt}[f(\tau)]\phi(t-\tau)d\tau \qquad (2)$$

If the step response of the system is known, equation 1, equation 2, or any of the other forms presented in the literature, may be used to find the response to an arbitrary input wave, depending on which form is easiest to evaluate.[7,8]

In general, the step response of an actual high-voltage measuring system cannot be expressed as a simple analytic function and the input wave generally has discontinuities and irregularities which make analytic evaluation of the superposition integral impractical. The integral may be evaluated numerically with the aid of a desk-type calculator however. This is done simply by considering the input wave to be composed of a series of successive step functions, each shifted in time by a constant interval, and then taking the sum of the step response amplitudes at the appropriate time. If the the step response and the applied wave are approximated as straight lines (Simpson's Rule) the bookkeeping may be done in the systematic manner[9] shown in Fig. 2. Figs. 2 and 3 illustrate the principles described. The number of steps into which the applied wave must be broken depends on the waveshapes of the applied and step response waves and on the degree of the detail desired in the calculated response wave. Generally, 30 to 50 steps are sufficient. If only a portion of the response waveshape is desired, only the summation calculations for that portion need be done. The summation calculation for each point is independent of the calculations for other points. A previous paper (reference 5, Fig. 17) gives an example of the accuracy that may be realized by such a numerical method.

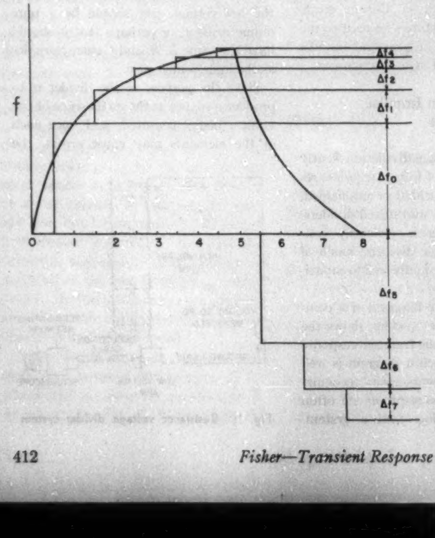

Fig. 2 (left). Representation of a wave by a series of step functions

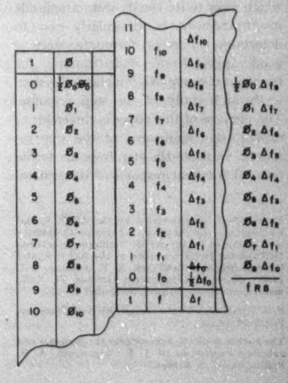
Fig. 3 (right). Numerical evaluation of a superposition integral

ϕ = amplitude of step response
f = amplitude of applied wave
f_R = amplitude of response wave



Response of Systems to Typical Impulse Waves

Next to a step function the ramp function, a function which increases indefinitely at a constant rate, is the simplest type of applied wave. This is particularly fortunate since many common waves may be visualized as combinations of ramps of various slopes or ramps and steps.

Since the ramp is the integral of the step it can be determined from the step response quite easily by numerical integration. In addition all ramps are related, since changing the slope by a factor *m* merely changes the amplitudes of the points on the response by a factor *m*.

Fig. 4 shows the step responses of four hypothetical systems and their corresponding ramp responses. In each case it will be noted that after the step response has reached its steady-state value the ramp response follows parallel to the applied ramp wave, but displaced by a time T. Hyltén-Cavallius and Romano[4,6] have pointed out that the time displacement T is equal to the net area enclosed between the step and the step response, considering areas below the unity axis positive and those above it negative. In system A, for instance, the time displacement T is equal to the area of the triangle A_1 ($A_1=1/2\times0.1\times1=0.05=T$).

Fig. 5 shows how some common waves may be visualized as combinations of ramps and steps. Since these waves are similar to those encountered during high-voltage impulse testing they will be called

Vol. 7
Pt. 1
1958

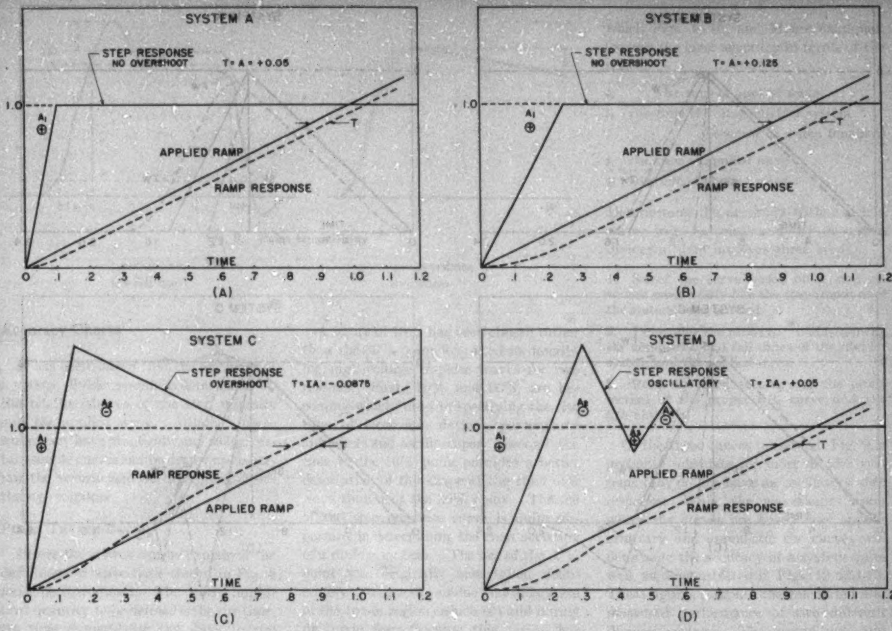


Fig. 4 (above). Step and ramp function response waves

full, triangular, and steep-front waves. Fig. 6 shows how three typical waves would be reproduced by the four systems of Fig. 4. Every time a change in slope or discontinuity is made in the applied wave, a disturbance is set up which lasts as long as the time that would be required for the step response to reach its steady-state value.

Often a divider is rated upon its ability to reproduce a steep-front wave with the tacit assumption that if it can do this correctly it will also reproduce any other wave correctly. Figs. 4, 6, and 7 illustrate that if an understanding of divider response is desired, more than just the crest accuracy of the response wave must be considered. They also illustrate the pitfalls of considering the response to only one type of wave.

Systems *A* and *D* of Fig. 4 both reproduce the steep-front wave with the same crest error, 5%, but the over-all shape of the response wave is quite different; Figs. 6(A) and 6(D). If studies were being made of some phenomena where the shape of the applied voltage wave was quite important, one could arrive at completely different conclusions depending on which divider system was used.

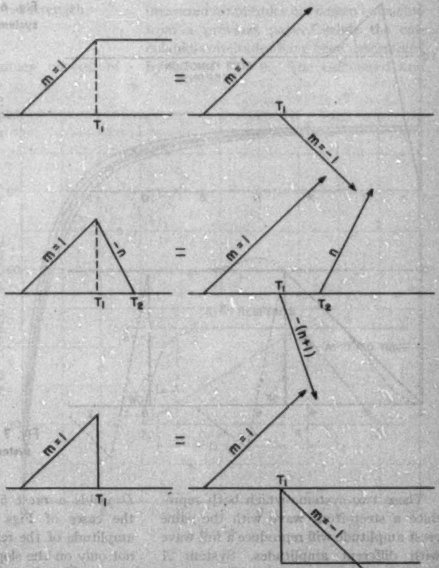

Fig. 5 (right). Representation of waves by ramp and step functions

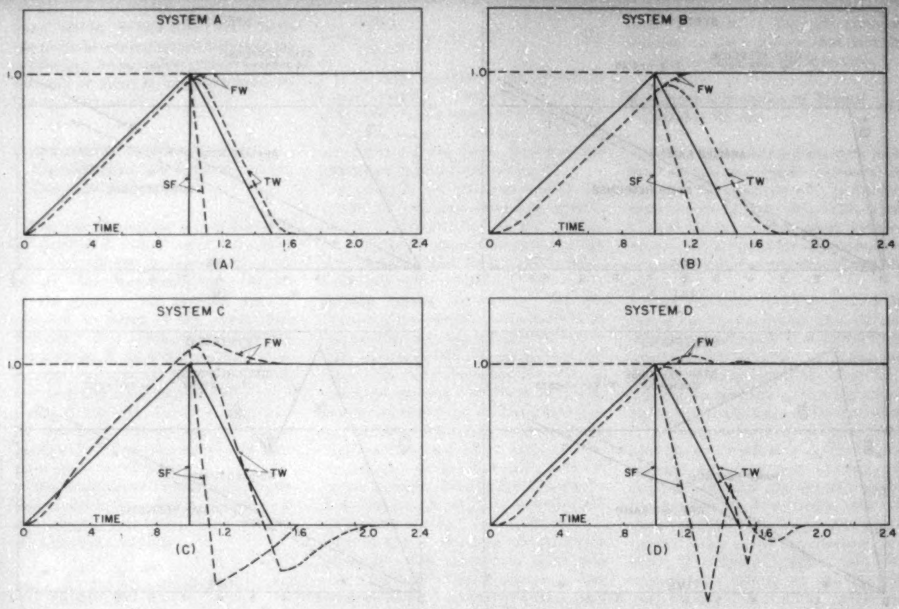

Fig. 6 (above). Response of systems of Fig. 4 to typical waves

——applied wave
– – –response wave
SF = steep-front wave
TW = triangular wave
FW = full wave

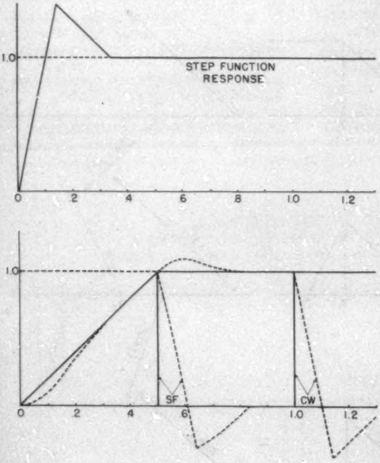

Fig. 7 (left). Response of a system in which ΣA = T = 0

These two systems which both reproduce a steep-front wave with the same crest amplitude will reproduce a full wave with different amplitudes. System *A* yields the correct amplitude, but system *D* yields a crest 5% too high. In all the cases of Figs. 4 and 6 the crest amplitude of the response wave depends not only on the slope of the front of the applied wave, but on the slope of the tail as well. For instance, the triangular wave is always reproduced with a greater crest amplitude than the steep-front wave.

Considering idealized steep-front waves, the crest error at chop time is equal to the vertical displacement between the ramp function and the ramp response of the divider system. In terms of the factors *A* and *T* of Fig. 4, the crest error is

$$\text{error} = 100\frac{T}{t}\%$$

where t is the chop time of the steep-front wave. Some investigators have implied that divider systems should deliberately be made oscillatory so that the total area between the step function and its response be zero ($\Sigma A = T = 0$), thus resulting in a zero crest error when measuring idealized steep-front waves. Fig. 7 illustrates a system with such a response. Although the steep-front wave is measured with no error the full wave or the wave chopped on the tail is measured with a crest 10% too high. If such a system were used to measure volt-time curves the indicated curves would be 10% high in the region where the applied wave was being chopped on the tail.

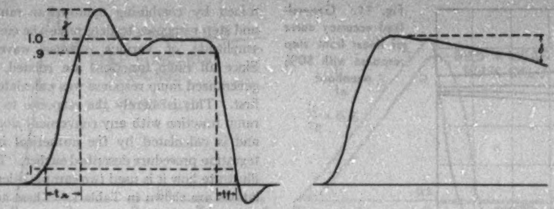

Fig. 8. Pulse terminology

t_r = rise time
t_f = fall time

γ = overshoot
δ = droop

Accuracy Charts

It has been shown that the accuracy of a voltage-divider system is determined by the relative shapes of the step response and the applied wave. Although these waves may have practically any shape, certain simple curves can be drawn up to permit the accuracy to be determined from the step response.

Pulse Terminology

Before the curves can be explained the definitions of waveshape shown in Fig. 8 must be introduced. The most important quantity to be defined is the rise time, the time required for the wave to rise from 10% to 90% of its final amplitude. The fall time is defined similarly. The terms overshoot and droop are self-explanatory.

A figure of 10% has been chosen rather than the 30% point long used in describing high-voltage impulse waves for two reasons. First, 10% and 90% are becoming widely used in specifying the rise time of electronic devices, particularly amplifiers and oscilloscopes. Second, the time to the 10% point provides a better description of the shape of the start of a wave than does the 30% point. The toe of the step response curve is quite important in determining the crest accuracy of a divider system. The use of the 30% point was originally undertaken deliberately to avoid undue consideration of the toe-in region, which is valid during dielectric tests because this region has little influence on dielectric strength.

Use and Significance

The generalized accuracy curves, of which Figs. 9, 10, and 11 are examples, express the crest accuracy in terms of the ratios:

$$\frac{t_1}{t_r} = \frac{\text{rise time of applied wave}}{\text{rise time of voltage-divider system}}$$
(response to a step function)

$$\frac{t_1}{t_2} = \frac{\text{rise time of applied wave}}{\text{fall time of applied wave}}$$

Determining the accuracy with which a wave will be measured by a given divider system involves three steps.

1. Select the curve based on a step response most nearly like the step response of the system being studied.

2. Determine the ratios t_1/t_r and t_1/t_2 using the actual rise and fall times of the divider system and the applied wave.

3. Read the crest accuracy at the intersection of the proper t_1/t_2 curve and the t_1/t_r abscissa.

Of the three curves presented, Fig. 9 is probably adequate for most divider systems that do not have an oscillatory step response. While the waveshapes upon which the curves are based may appear arbitrary and unrealistic the curves will determine the accuracy of a system quite well, as demonstrated in Figs. 12 and 13. These figures compare the calculated and measured performance of two different divider systems. The waveforms and measured amplitudes have been extracted from a previous paper,[8] while the calculated amplitudes have been determined by use of Fig. 9. The calculated and

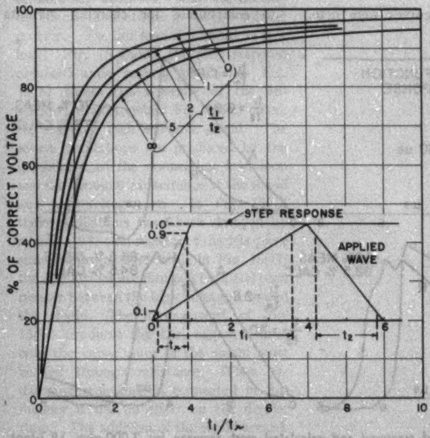

Fig. 9. Generalized accuracy curve

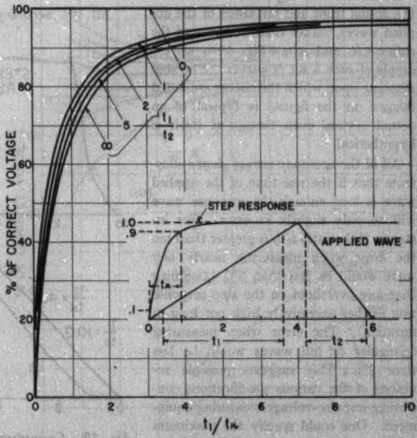

Fig. 10. Generalized accuracy curve of exponential front step response

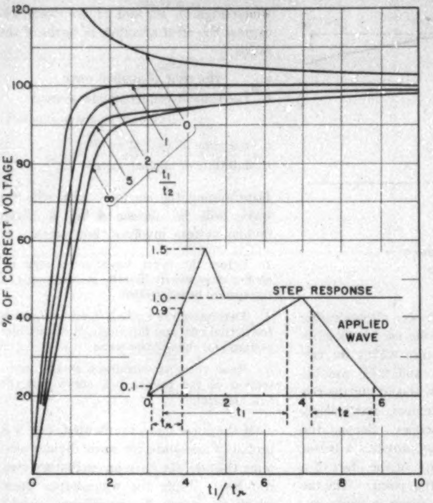

Fig. 11. Generalized accuracy curve of linear front step response with 50% overshoot

measured crest amplitudes agree quite closely in all cases.

Figs. 9, 10, and 11 are suitable for general use since they are presented in terms of the dimensionless ratios t_1/t_r and t_1/t_2. If the response of an actual system has been determined curves may be drawn up which are more accurate, but are valid only for that particular system. Such curves could be presented in terms of the actual front and fall times of the applied waves, rather than in terms of the ratios t_1/t_r and t_1/t_2. Fig. 14 is an example of such a set of curves. The step response upon which the curves are based (shown on the figure) is typical of an actual system even though it itself is hypothetical.

All of the accuracy curves shown illustrate that if the rise time of the applied wave is long enough the response wave will be only slightly in error. For instance, if the ratio t_1/t_r is greater than ten the error when measuring nearly any wave would be less than 5% (assuming that any overshoot on the step response was neither excessively high nor long in duration). The error when measuring triangular or full waves would be less than 3%. This suggests possible revisions of the various specifications concerning impulse-voltage-measuring equipment. One could specify the maximum allowable rise time and overshoot that a measuring system would be allowed for use in measuring a given set of impulse waves or one could specify the minimum rise and fall times of an applied wave that could be measured with a piece of equipment having a given rise time. Either set of specifications would assure that the amplitude of the indicated response wave would be within the allowable limits of error.

CALCULATION OF CHARTS

All the accuracy curves were determined by combining appropriate ramp and step responses to determine the crest amplitude of various reponse waves. Since all ramp functions are related, a generalized ramp response was calculated first. This is merely the response to a ramp function with any convenient slope and is calculated by the numerical integration procedure described earlier. To illustrate how it is used two sample calculations are shown in Table I. These are calculations for the two points, $t_1/t_r=5$, $t_1/t_2=\infty$ and $t_1/t_r=5$, $t_1/t_2=1$, of Fig. 9. The amplitudes of the step function response and the generalized ramp response are those of Fig. 4(A). Calculating the response amplitude at other points is just a matter of combining ramp functions of the proper slope, as shown in Fig. 5.

RESPONSE OF CERTAIN PRACTICAL DIVIDERS

While it has been shown[5] that uncompensated resistance dividers are adequate for measuring the types of impulse waves encountered during acceptance tests on most apparatus it is sometimes necessary to build divider systems with higher performance capabilities. The following section will show how the performance of various compensating devices may be evaluated in terms of their effect on the step function response. All of the step-function-response oscillograms shown were obtained by the methods outlined in the Appendix.

The most common type of compensating device is a shield near the line end to compensate for charging currents

through the ground capacitance. To show the effects of a line shield on the step response, a 21,000-ohm divider was assembled. The high-voltage arm consisted of six vitreous enameled resistors $8^1/_2$ inches long by 3/4 inch in diameter with essentially noninductive windings. The low-voltage arm was simply the 75-ohm deflection cable and its noninductive terminating resistors, thus eliminating the effect of inductance in the low-voltage resistor. The line lead was about 14 feet long. Fig. 15 shows the step response obtained under several conditions. Fig. 15(A) shows the response of the unshielded divider, while Fig. 15(B) shows the response with a simple shield. The severe oscillations are produced by the inductance of the connecting lead loop and the terminal capacitance of the shield and high-voltage arm. In Fig. 15(C) these oscillations have been damped by adding a 500-ohm resistor at the test-piece end of the line lead while in Fig. 15(D) the oscillations are damped by a 500-ohm resistor between the high-voltage arm and the shield. The arrangement of Fig. 15(D) produces the best response since only the capacitance of the shield must be fed through resistance. When the damping resistance is connected in this manner it has no effect on the divider ratio. The addition of the shield according to the arrangement of Fig. 15(D) improved the rise time from 0.091 μsec (microsecond) to 0.023 μsec. If a restriction were made that a steep-front wave must be measured with no more than 5% error the unshielded divider would be suitable for waves cresting at 0.91 μsec (t_1=0.73 μsec) while the shielded divider of Fig. 15(D) would be suitable for waves cresting at 0.28 μsec (t_1=0.23 μsec). The performance of the unshielded divider is best estimated from Fig. 10 and the performance of the shielded divider of Fig. 15(D) is best estimated from Fig. 9.

The response of a divider may sometimes be improved by the use of suitable wave-shaping networks in the low-voltage arm. If the response voltage, as developed across a pure ohmic resistor, rises exponentially as in Fig. 16(A) the step response may be improved by inserting an inductor in series with the low-voltage resistor in much the same way as the response of a video amplifier may be improved by the use of peaking coils. Figs. 16(A) and 16(B) show the response of a 10,000-ohm divider suitable for 3,500 kv. The high-voltage arm consisted of 67 resistor cards each holding 8 inches of resistance winding. The total inductance of the high-voltage arm was about 270 microhenrys and the total capacitance to ground about 150 micromicrofarads. Since the divider system was to be used with a short line (15 feet) lead the high-voltage arm was folded near the center and the top portion run horizontally until it was close to the pulse generator.

Fig. 16(A) shows the response with the output of the high-voltage arm fed directly into the deflection cable. Since the output current of the high-voltage arm is essentially independent of the resistance of the low-voltage arm the same response would be developed if a pure ohmic resistor were used as the low-volt-

age arm. Fig. 16(A) shows the response when a 5-ohm noninductively wound resistor in series with an inductance of 0.4 microhenry was used as the low-voltage arm. The rise time was improved from 0.33 µsec to 0.14 µsec by the addition of 0.4 microhenry in the low-voltage arm.

If a divider system is underdamped and has an oscillatory step response the general shape of the response may be improved (but not the rise time) by the circuit shown in Fig. 17. Fig. 17(A) shows the response of a 4,500-ohm divider with a high-voltage arm consisting of resistors each containing 8 inches of resistance winding. The line lead was 14 feet long. Fig. 17(B) shows the response with the wave-shaping network inserted. The overshoot and oscillations have been practically eliminated.

The effects of such modifications or compensating features cannot be calculated practically. Their effect on the step function response may, however, be determined experimentally and thus re-

lated to their effects on crest accuracy by means of the procedures described in this paper.

Conclusions

1. The accuracy of an impulse voltage divider system depends on the shapes of the applied wave and the response of the system to a step function. It depends primarily on the two ratios:

$$\frac{t_1}{t_r}=\frac{\text{rise time of applied wave}}{\text{rise time of voltage divider system}}$$

$$\frac{t_1}{t_2}=\frac{\text{rise time of applied wave}}{\text{fall time of applied wave}}$$

2. Curves are presented which show the relationships between these ratios and the crest accuracy.

3. Methods presented herein provide a powerful tool for determining the measuring capabilities of impulse voltage dividers and for investigating the effects of compensating features.

Appendix. Determination of Step Response

The response of nearly all impulse voltage dividers may be obtained by applying a low-voltage (100-volt) rectangular pulse to the divider and measuring the response with an oscilloscope incorporating a high-speed amplifier. The pulse should reach its crest as rapidly as possible and have negligible droop on the tail. Generally speaking, the rise time of the front should be five to ten times as fast as the expected rise time of the divider system. The pulse should last at least as long as it takes for the divider system to reach steady-state conditions. Many vacuum-tube square-wave generators meet these requirements. A type of pulse generator well suited to the purpose incorporates a transmission line charged to about 400 volts and then discharged into a load resistor through a switch with mercury wetted contacts. Such pulse generators can produce rectangular waves rising to crest in 1 to 3 mμsec (millimicroseconds) and lasting for several microseconds.

The true waveshape of the applied pulse may be determined by applying it directly to the vertical deflection plates of the oscilloscope. If the waveshape is satisfactory it may be applied to the oscilloscope through an attenuator to check the oscilloscope. The amplified wave should rise to its crest in 10 to 20 mμsec with negligible overshoot and should not droop on the tail. The sensitivity should be great enough to produce a usable deflection with an input of 0.1 volt.

The pulse should be applied with the divider and its ground and line leads in approximately the position they will occupy in service. The line lead should not be run too close to the body of the divider. The output of the divider should be fed through the appropriate length of coaxial cable to the oscilloscope to preserve the time relationships existing in actual service.

If the rise time of the divider system is short compared to the rise times of the amplifier or the applied step function pulse the indicated rise time will be too high. An approximate correction may be made, however, from the relation

$$t_r=\sqrt{(t_{r1})^2+(t_{r2})^2+(t_{r3})^2+\ldots\ldots} \qquad (3)$$

where

t_r = over-all rise time of the system
t_{r1}, t_r, t_{tr3}, etc. = rise times of the individual components of the system

Discussion

J. H. Park (National Bureau of Standards, Washington, D. C.): This paper, together with reference 5 of the paper, demonstrates quite conclusively the importance of the square-wave response method for investigating divider accuracy. It should, I feel, by now be quite evident that this method is to be preferred over the sustained-frequency-response method. However, it does not offer a possibility of investigating all of the short-time surge-measurement problems.

There must be some minimum divider response time that can be accurately measured with the method. This limit is apparently set by the rise time of the oscillograph amplifier which the author gives as between 10 and 20 mμsec. When using such an amplifier, any measurement of divider response time less than 0.02 μsec would be questionable. Thus for accurately measuring peak voltages occuring in less than 0.1 μsec this method would appear to be unsuitable.

The main disadvantage of relying on the square-wave-response method completely is that it gives no indication of factors such as voltage coefficient of resistance and pulse corona discharges from the divider which became troublesome at high voltage only.

N. Hyltén-Cavallius (Allmänna Svenska Elektriska Aktiebolaget, Ludvika, Sweden): May I compliment the author on a most interesting and valuable paper. I agree with it entirely but would like to discuss two points which may be of some practical importance.

The author states that a system with $\Sigma A=T=0$ will give too high measured values when measuring full impulses. This is, of course, quite true but the practical problem in general is related to:

1. The measurement of the amplitude of impulses chopped on the front down to, say, 0.4 μsec with an error less than, say, 5%.

2. The measurement of the amplitude of full impulses with front times down to, say, 0.5 μsec with an error less than 3%.

The first measurement requires a system having $\Sigma A \leq 20$ mμsec. It is possible to build such dividers for 1 megavolt and even for higher voltages but in general only if some overshoot is permitted. As an example, consider a shielded resistor divider for about 1 megavolt used in our works. It has $\Sigma A \simeq 15$ mμsec, an overshoot of about 20%, and a subsequent undershoot of about 10%. The time for the response to reach its stationary value is about 200 mμsec.

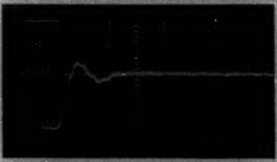

Fig. 18. Response for shielded resistor divider

The response is shown in Fig. 18 having 100-mμsec time sweep per vertical line. It can be shown by an extension of Mr. Fisher's own Fig. 7 (or preferably by Fig. 3) that the error when measuring a full impulse according to item 2 with a front time of 0.5 μsec or longer will be definitely negligible. Actually it is less than 1%.

As it is very practical to use the same divider both for full and front chopped impulses, I do not think a useful type of divider should be forbidden. A condition should, of course, be that the front of the impulse to be measured be a number of times longer than the time for the response to reach approximately its stationary value.

The author states that the 10–90% points are more useful than 30–90% for the definition of rise time. I agree entirely with this but do not understand the statement about the toe of the response and its relevance to the 10 or 30% level. The shape of the toe is quite important (we used to speak in terms of "slope at $t=0$") but it is in principle not possible to obtain any information about the shape of the toe by defining just one point on it. (The 90% level has no relevance to the toe.) It would be of interest to have some information about this.

F. A. Fisher: As Mr. Park points out, the minimum divider rise time that may be measured accurately is set by the rise time of the oscillograph amplifiers and is thus in the range of 10 to 20 mμsec for the equipment used. However, even if the rise time of the divider system is less than the rise time of the amplifier, considerable information may be gained about the shape of the actual divider step response. The indicated rise time may be approximately corrected by use of equation 3 of the paper. Thus if the indicated rise time were 16 mμsec and the amplifier rise time were 12 mμsec, the true divider rise time would be 10.5 mμsec. Oscillations on the divider step response would still be reproduced, although with lower amplitude.

Low-voltage techniques, of course, may not completely define the actual high-voltage response. A satisfactory high-voltage test procedure would be a valuable contribution to the art.

Mr. Hyltén-Cavallius' points on dividers with an oscillatory step response are well taken. I agree that such a divider would be satisfactory for measuring full waves as long as the time to crest is several times as long as the time required for the divider step response to reach its steady-state value. It should continually be kept in mind, however, that such dividers may lead to errors when measuring full waves if the front time of the full wave is short.

Mr. Hyltén-Cavallius also comments on the remarks dealing with the definitions of rise time. Actual high-voltage impulse waves often have fairly high amplitude oscillations near the start or toe of the wave which do not affect the dielectric strength of a test sample. Since the amplitudes of these oscillations are generally less than 30%, it is common practice to define the effective front time in terms of the 30% and 90% points. Similar oscillations at the beginning of a divider step-response wave would have an effect on the over-all transient response of the divider system. Defining the rise time in terms of the 10% and 90% points better reflects the effect of such oscillations on the over-all rise time.

Matrix Programming of Electronic Analog Computers

R. E. HORN
ASSOCIATE MEMBER AIEE

P. M. HONNELL
FELLOW AIEE

MATRIX PROGRAMMING of differential equations for electronic analog computers organizes the equations, thereby minimizing chances for errors; simplifies the scaling of coefficients and variables to suit the characteristics of the available machine; and in many instances permits the reduction of the number of "sign changers." The matrix method furthermore helps safeguard against the appearance of extraneous terms in the solutions of certain systems of differential equations. These very practical attributes of the matrix method of programming save computing time and equipment.

The key concept in the theory of matrix methods of programming electronic analog computers lies in the establishment of the 1-to-1 reciprocal correspondence between the matrically formulated differential equations and the synthesized electronic computer networks.[1–3] The generality of the matrix method leads not merely to one or two, but to a large group of electronic synthesis networks all yielding the solution to a given differential equation problem.

The object of this paper is to indicate by specific examples arising in practice the advantages of the matrix programming of electronic analog computers.

In the first example a wind-tunnel problem illustrates the organization, scaling of coefficients, and reduction of negative signs, thus minimizing the need for sign-changing amplifiers in a high-order system of differential equations.

This is followed by an elementary example exhibiting the care which must be taken in programming certain systems of differential equations to preclude the appearance of extraneous roots in the determinantal equation, and thereby extraneous solutions to the equations. This particularly insidious phenomenon may arise from devotion to the common "solve for the highest derivative" routine for synthesis of computer networks. These extraneous solutions are sometimes manifest as "drift" rather than in their true nature. Furthermore, the identical computer network sometimes yields "solutions" which are correct, and sometimes incorrect, depending upon the initial conditions. This is illuminated by a specific example.

Elementary Matrix Transformations

The objectives of some linear transformations of systems of linear algebraic equations and first-order differential equation systems of particular usefulness in analog computers are: 1. changing the magnitudes or signs of the coefficients of the terms in the equations, and 2. scaling in magnitude or changing the signs of the prescribed functions or dependent variables. Of course, such changes as are made must yield solutions unchanged or easily related to the original problem equations. The need for these transformations is often dictated by the purely electrical characteristics of the computer or recording equipment, such as the allowable output voltage range of the amplifiers. These elementary transformations are illustrated by the following example.

Example 1. The design of a wind-tunnel control system using analog computer techniques requires synthesis of the equations describing tunnel performance and the experimental determination of desirable controller characteristics. The particular wind-tunnel considered in this

Paper 58-66, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted September 3, 1957; made available for printing November 7, 1957.

R. E. HORN is with Westinghouse Electric Corporation, Baltimore, Md., and P. M. HONNELL is with Washington University, St. Louis, Mo.

example may be adequately represented by the following differential equation system, in which P represents the pressures developed as a function of the prescribed variables, A and N_0. (The differential coefficient d/dt is represented by d.)

$$(1.90+d)P_3-0.423P_4-1.59P_{ac}=-0.303A_{13} \quad (1)$$

$$-0.433P_3+(4.51+d)P_4-1.87P_{md}-0.331P_m-4.16P_p=23.7A_{30}-1.29N_0 \quad (2)$$

$$-58.1P_3+(74.9+d)P_{ac}-30.8P_p=155N_0 \quad (3)$$

$$-1.01P_4+(0.124+d)P_{md}-7.52P_s=0.302N_0 \quad (4)$$

$$(0.309+d)P_{mi}-0.159P_m=37.8N_0 \quad (5)$$

$$-0.483P_{mi}+(0.617+d)P_m=-106.A_{30}-108.A_{33} \quad (6)$$

$$-0.00514P_3-0.091P_{ac}+(2.97+d)P_p-0.973P_s=0.173.A_{13}-2.18N_0 \quad (7)$$

$$-15.6P_{md}+(16.3+d)P_s=0 \quad (8)$$

$$151.P_p-54.3P_s+10^6P_n/P_p=0 \quad (9)$$

Valve openings which determine pressure are represented by A and are assumed to be controlled by functions of the differences between desired pressures P_{ms}, P_{ss}, or pressure ratio $(P_n/P_p)_s$, and respective measured values P_m, P_s, (P_n/P_p). Controller characteristics may be represented functionally by the following equations

$$A_{33}=f_1(P_{ms}-P_m) \quad (10)$$

$$A_{30}=f_2(P_{ss}-P_s) \quad (11)$$

$$A_{13}=f_3[(P_n/P_p)_s-(P_n/P_p)] \quad (12)$$

To illustrate application of the matrix technique to this problem, the synthesis procedure for this 8th-order system is described. Inclusion of controller characteristics involves an addition to the basic matrix equation and is not essential for the purpose of the present example.

An equivalent matrix representation of the system of equations 1 through 9 is indicated in equation 13 (see below).

The problem is to adjust the coefficients to reasonable values for use with a particular computer. Since the dependent variables are not known a priori, the term reasonable initially involves a "best guess" that tends to keep both the magnitude of the coefficients and dependent variables within acceptable limits. A convenient method is to apply transformations that attempt to establish coefficients approaching unity. For the majority of electronic analog computers, the step between the final mathematical form and the synthesis then involves the introduction of a factor of 10^{-6} in all terms, thus permitting immediate interpretation in terms of computer component values expressed in microfarads and micromhos, and computer variables expressed in volts and microamperes.

In equation 13 premultipliers affecting rows 3, 8, and 9, as follows:

row 3—divide by 100
row 8—divide by 10
row 9—divide by 100

result in reasonable values for all terms except that in row 9, column 9, which remains beyond normal limits. For cases of this type application of postmultipliers affecting columns in the coefficient matrix and also the dependent variables achieves the desired result. In particular, applying the column transformation

column 9—divide by 1,000

completes the coefficient adjustment necessary in equation 13.

Treatment of coefficients having an associated negative sign conventionally requires an additional amplifier to act as a sign changer. Reduction of the number of such sign changer is of advantage from both equipment and stability standpoints. Using the matrix formulation, transformations changing sign are easily applied and the effects of each transformation relative to the reduction of minus signs is immediately evident. Although unnecessary mathematically, electronic network stability usually dictates that transformation of rows and columns are made in pairs thus maintaining principal diagonal terms with positive sign. Desirable transformations for equation 12 change the signs of:

row 1, column 1
row 4, column 4
row 6, column 6
row 7, column 7
row 9, column 9

The number of sign changers has now been reduced from 17 to one.

Results of the application of both scale-factor and sign-change transformations are indicated in equation 14 (see previous page), which is equivalent to equation 13 but more applicable to analog computer synthesis.

If equation 13 is represented as

$$[f_0][x_0]=[y_0] \tag{15}$$

and equation 14 as

$$[f_1][x_1]=[y_1] \tag{16}$$

equations 17 through 19 represent the elementary transformations.

$$[f_1]=\begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.01 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -0.01 \end{bmatrix}[f_0]\begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -0.001 \end{bmatrix} \tag{17}$$

$$[x_1]=\begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1{,}000 \end{bmatrix}[x_0] \tag{18}$$

$$[y_1]=\begin{bmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.01 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -0.01 \end{bmatrix}[y_0] \tag{19}$$

In view of their elementary character, the matrix premultipliers and postmultipliers in equations 17 through 19 need not be written down explicitly, although the information they contain, especially in the last, must be recorded.

The electronic network equation corresponding to equation 14 is indicated in equation 20, in which the coefficients now represent micromhos and microfarads, and the resultant ideograph is shown in Fig. 1.

Extraneous Solutions

The elementary solve-for-the-highest-derivative technique of computer programming, although restricted in form, usually gives correct solutions, particularly for single nth-order differential equations. In systems of differential equations, however, great care must be exercised to avoid extraneous solutions.

It is known that differentiation of equations in a system may introduce additional roots in the determinantal equation, and thus alien solutions. This constraint is easily overlooked in attempting to program a computer according to the currently accepted methods which require that each equation be written in such a manner that a derivative of a dependent variable appears to be a known function. Then, assuming the dependent variables are known, successive integrations are performed, functions combined, and eventually "fed back," completing the synthesis network. This common technique is not applicable to many systems of equations and the differentiation required in attempting to apply the method may easily yield erroneous results. Example 2 is an elementary illustration of this type of programming error.

Example 2. The following system of differential equations

$$\begin{aligned} &d^2x+d^2y-d^2z+dy+x+y=0 \\ &dy+z=0 \\ &2dx+dz+z=0 \end{aligned} \tag{21}$$

has the determinantal equation

$$\lambda(\lambda+1)(\lambda^2+1)=0 \tag{22}$$

and the general solution

$$\begin{aligned} &x=\frac{(c_3-c_2)}{2}\cos t-\frac{(c_2+c_3)}{2}\ \sin t-c_4 \\ &y=c_1e^{-t}-c_2 \sin t+c_3 \cos t+c_4 \\ &z=c_1e^{-t}+c_2 \cos t+c_3 \sin t, \end{aligned} \tag{23}$$

in which the four constants specified in equation 23 are determined by the conditions

$$\begin{aligned} &x(0)=\frac{(c_3-c_2)}{2}-c_4 \\ &y(0)=c_1+c_3+c_4 \\ &z(0)=c_1+c_2 \\ &dx(0)=-\frac{(c_2+c_3)}{2} \end{aligned} \tag{24}$$

It may appear desirable to differentiate the second and third equations of equation 21 yielding a set of equations which may then be programmed without difficulty using the conventional procedure.

The new system reads

$$\begin{aligned} &d^2x+d^2y-d^2z+dy+x+y=0 \\ &d^2y+dz=0 \\ &2d^2x+d^2z+dz=0 \end{aligned} \tag{25}$$

and has the determinantal equation

$$\lambda^3(\lambda+1)(\lambda^2+1)=0 \tag{26}$$

and the general solution

$$\begin{aligned} &x=\frac{(c_3-c_2)}{2}\cos t-\frac{(c_2+c_3)}{2}\ \sin t-(c_4+c_5)-c_6t \\ &y=c_1e^{-t}-c_2 \sin t+c_3 \cos t+c_4+c_6t \\ &z=c_1e^{-t}+c_2 \cos t+c_3 \sin t+c_5 \end{aligned} \tag{27}$$

$$\begin{bmatrix} (1.90+d) & 0.423 & 1.59 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.433 & (4.51+d) & 0 & 1.87 & 0 & 0.033 & 4.16 & 0 & 0 \\ 0.581 & 0 & (0.749+0.01d) & 0 & 0 & 0 & 0.308 & 0 & 0 \\ 0 & 1.01 & 0 & (0.124+d) & 0 & 0 & 0 & 7.52 & 0 \\ 0 & 0 & 0 & 0 & (0.309+d) & 0.159 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.483 & (0.617+d) & 0 & 0 & 0 \\ -0.005 & 0 & 0.091 & 0 & 0 & 0 & (2.97+d) & 0.973 & 0 \\ 0 & 0 & 0 & 1.56 & 0 & 0 & 0 & (1.63+0.1d) & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1.51 & 0.543 & 1 \end{bmatrix}\begin{bmatrix} -w_1 \\ -w_2 \\ -w_3 \\ -w_4 \\ -w_5 \\ -w_6 \\ -w_7 \\ -w_8 \\ -w_9 \end{bmatrix}=\begin{bmatrix} j_1' \\ j_2' \\ j_3' \\ j_4' \\ j_5' \\ j_6' \\ j_7' \\ j_8' \\ j_9' \end{bmatrix} \tag{20}$$

Fig. 1. Ideograph of equation 20

The six constants in equation 27 are related to the initial conditions by the relations

$$
\begin{aligned}
x(0) &= \frac{(c_3 - c_2)}{2} - c_4 - c_6 \\
y(0) &= c_1 + c_3 + c_4 \\
z(0) &= c_1 + c_2 + c_5 \\
dx(0) &= -\frac{(c_2 + c_3)}{2} - c_5 \\
dy(0) &= -c_1 - c_2 + c_6 \\
dz(0) &= -c_1 + c_3
\end{aligned}
\qquad (28)
$$

Comparison of the solution in equation 23 with that in equation 27 clearly indicates the appearance of extraneous constant and linear terms in the latter.

In the general situation, the solutions to the differential equation system are not known explicitly (else why use the computer?). This leads to the following interesting situation. Assume that the conventional technique has been followed and the computer set up according to the differentiated system equation 25. Now suppose the transient response to the initial conditions

$$
\begin{aligned}
x(0) &= 20 \\
y(0) &= z(0) = dx(0) = 0
\end{aligned}
\qquad (29)
$$

is desired. Then the solutions given by equations 23 and 27 both read

$$
\begin{aligned}
x &= \frac{1}{3}(20 \cos t + 40) \\
y &= \frac{1}{3}(20e^{-t} + 20 \cos t + 20 \sin t - 40) \\
z &= \frac{1}{3}(20e^{-t} - 20 \cos t + 20 \sin t),
\end{aligned}
\qquad (30)
$$

i.e., either system yields the identical solution.

Next, consider the solution for the initial conditions

$$
\begin{aligned}
x(0) &= y(0) = z(0) = 0 \\
dx(0) &= 20
\end{aligned}
\qquad (31)
$$

The solution in equation 23 to the original problem of equation 21 now yields

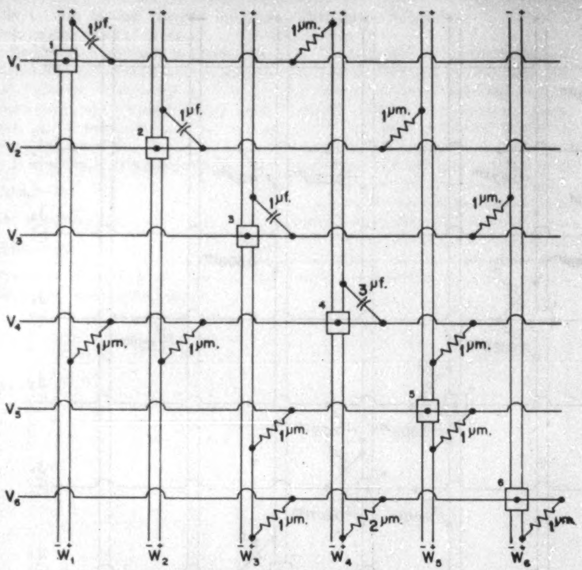

Fig. 2. Ideograph of equation 34

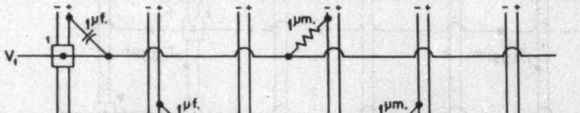

Fig. 3. Ideograph of equation 38

$$
\begin{aligned}
x &= 20 \sin t \\
y &= 20e^{-t} + 20 \sin t - 20 \cos t \qquad (32) \\
z &= 20e^{-t} - 20 \sin t - 20 \cos t
\end{aligned}
$$

whereas equation 27 yields the distinctly different solution

$$
\begin{aligned}
x &= \frac{1}{3}(20 \sin t + 40\, t) \\
y &= \frac{1}{3}(-20e^{-t} + 20 \sin t - 20 \cos t + \\
&\qquad 40 - 40t) \qquad (33) \\
z &= \frac{1}{3}(-20e^{-t} - 20 \sin t - 20 \cos t + 40)
\end{aligned}
$$

Recalling that the computer has been set up according to the common technique, i.e., according to equation 25, it is clear that the computing machine (which merely exhibits graphical plots) will in the first instance, equations 29 and 30, yield correct solutions to the ostensible problem in equation 21. In the second instance, equation 31, the computer exhibits solutions which do not satisfy the original problem in equation 21.

Of course, many other combinations of initial conditions are possible; but the machine never divulges which are indeed the correct solutions to the original problem, and which are not. This must be ascertained by other means. In this instance, the unwary may easily be misled, for as shown, sometimes the correct solutions are obtained, and sometimes they are not.

The matrix formulation of the problem, however, places in a clearer light the well-known mathematical requirements on transformations such that any synthesized computer network, if stable, yields the solutions to the original problem. This is indicated in the next section, together with oscillograms of computer solutions to the differential equation problem of equations 21 and 25 programmed by the matrix method.

Matrix Programming

The matrix programming of the differential system of equation 21 has been indicated and explained in reference 1, and one version leads to the equation

$$
\begin{bmatrix} d & 0 & 0 & -1 & 0 & 0 \\ 0 & d & 0 & 0 & -1 & 0 \\ 0 & 0 & d & 0 & 0 & -1 \\ 1 & 1 & 0 & 3d & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 2 & 0 & 1 \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \\ -w_3 \\ -w_4 \\ -w_5 \\ -w_6 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \qquad (34)
$$

which is illustrated by the ideograph of Fig. 2. It therefore suffices to synthesize the differentiated system of equation 25.

According to the method outlined in the

the first reference, equation 25 may be written as

$$\left\{\begin{bmatrix}1&1&0\\0&0&0\\0&0&0\end{bmatrix}+\begin{bmatrix}0&1&0\\0&0&1\\0&0&1\end{bmatrix}D+\begin{bmatrix}1&1&-1\\0&1&0\\2&0&1\end{bmatrix}D^2\right\}\begin{bmatrix}x_1\\x_2\\x_3\end{bmatrix}=\begin{bmatrix}0\\0\\0\end{bmatrix} \qquad (35)$$

in which x_1, x_2, and x_3 represent x, y, and z respectively.

One first-order system equivalent to equation 35 reads

$$\begin{bmatrix}d&0&0&-1&0&0\\0&d&0&0&-1&0\\0&0&d&0&0&-1\\1&1&0&d&(1+d)&-d\\0&0&0&0&d&1\\0&0&0&2d&0&(1+d)\end{bmatrix}\begin{bmatrix}-w_1\\-w_2\\-w_3\\-w_4\\-w_5\\-w_6\end{bmatrix}=\begin{bmatrix}0\\0\\0\\0\\0\\0\end{bmatrix} \qquad (36)$$

Since this is likely to be unstable on existing analog computers, see reference 2, equation 36 may be premultiplied by

$$\begin{bmatrix}1&0&0&0&0&0\\0&1&0&0&0&0\\0&0&1&0&0&0\\0&0&0&1&-1&1\\0&0&0&0&1&0\\0&0&0&-2&2&1\end{bmatrix} \qquad (37)$$

resulting in the matrix equation 38 which may be synthesized without difficulty and is stable.

$$\begin{bmatrix}d&0&0&-1&0&0\\0&d&0&0&-1&0\\0&0&d&0&0&-1\\1&1&0&3d&1&0\\0&0&0&0&d&1\\-2&-2&0&0&-2&3(1+d)\end{bmatrix}\begin{bmatrix}-w_1\\-w_2\\-w_3\\-w_4\\-w_5\\-w_6\end{bmatrix}=\begin{bmatrix}0\\0\\0\\0\\0\\0\end{bmatrix} \qquad (38)$$

Fig. 3 is an ideograph of the electronic computer synthesis network corresponding to equation 38, and may be compared with Fig. 2.

Comparison of solutions exhibited by an analog computer for the two sets of differential equations corroborate the assertions of the previous section.

Figs. 4(A) and (B) respectively show the computer solutions to equations 21 and 25 programmed according to the matrix equations 34 and 38 for initial conditions of equation 29. As stated, the machine solutions coincide in this case.

For the initial conditions of equation 31, the oscillograms Figs. 5(A) and (B) correspond respectively to equations 32 and 33. As predicted, there is now no correlation between the respective solutions exhibited by the computer.

Résumé

The practical merits of the matrix programming of analog computers have been briefly demonstrated in this paper. The most elementary of matrix transformations are an invaluable time- and equipment-saving process, as the first example indicates.

With regard to the second example and the introduction of extraneous roots in a system of differential equations, so strikingly demonstrated by the oscillograms, again matrix methods are extremely valuable.

It is well known that to obtain equivalent differential equation systems, the determinant of the transformation matrix must be a constant. In particular, the system of equation 38 may be obtained directly from equation 34, if the latter is premultiplied by the matrix

$$\begin{bmatrix}1&0&0&0&0&0\\0&1&0&0&0&0\\0&0&1&0&0&0\\0&0&0&1&0&0\\0&0&-1&0&d&0\\0&0&-3&-2&0&3d\end{bmatrix} \qquad (39)$$

The determinant of equation 39 is $3d^3$.

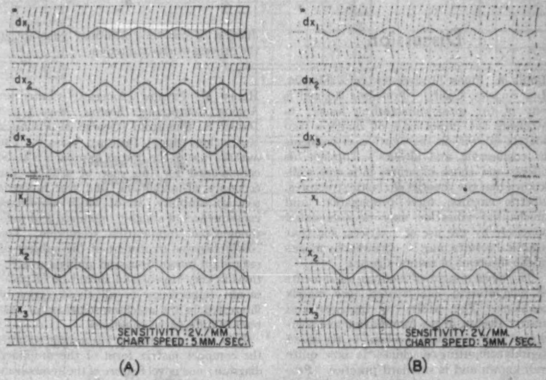

Fig. 4. Oscillograms for initial conditions of equation 31

A—Programmed according to equation 21
B—Programmed according to equation 25

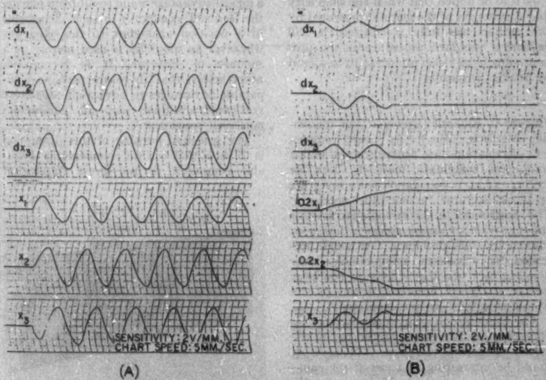

Fig. 5. Oscillograms for initial conditions of equation 31

A—Programmed according to equation 21
B—Programmed according to equation 25

Clearly this is not a constant and accounts for the extraneous λ^3 term in the determinantal equation 26, and additional terms in the solution equation 33.

In many practical problems which contain equations that have been differentiated for programming purposes, the manner of excitation of the network and initial conditions are such that the terms corresponding to the extraneous roots should have zero coefficients. However, whether due to initial or residual charges on the capacitors, grid current, internal parasitic coupling, or inexact matching of components, a small constant or linear term may be excited in addition to the correct solution response. The presence of such linear terms in the exhibited solution may then be interpreted as amplifier "drift," rather than actually as an incorrect synthesis network. This is the situation which may easily arise as indicated by the second example.

Finally, it should be clear that the application of matrix methods to analog computer programming are of far wider scope and generality than can be indicated in this brief introduction. But the practicality of the matrix method is clearly established. If not employed, the most economic operational use of the machine is not realized. This is the antithesis of the *raison d'être* for the computing machine in the first place!

◆

Discussion

Louis A. Pipes (University of California, Los Angeles, Calif.): Professor Honnell is one of the most outstanding leaders in stressing the importance of matrices and matrix calculus in the solution of problems in engineering and physics. Through his efforts and those of others it is now well-known that the theories of elastic structures, electric circuits, wave propagation, and mechanical vibration may be formulated concisely by the use of matrices, and that practical results may be obtained by means of the theorems of matrix algebra.

The development of modern instruments of computation has created new matrix problems. The utility of matrices and matrix algebra in the formulation and solution of many physical problems by the use of digital computing machines is now quite well known and is standard practice. Professor Honnell and Dr. Horn are to be congratulated for demonstrating the power and elegance of matrix methods in systematizing the programming of physical problems in analog computing machines.

It is to be hoped that when the simplicity and conciseness of the method presented by the authors are fully recognized, it will become a standard procedure in the programming of physical problems to be solved by analog computers.

Vincent C. Rideout (University of Wisconsin, Madison, Wis.): As more complex sets of equations are attempted on analog computers, systematic methods, both for scaling and for manipulation prior to setting up block diagrams, become more necessary. The matrix methods introduced in this paper provide a valuable guide to those confronted by such problems. Although presented for equations representing linear systems, they are also of help in nonlinear system study, if linearized forms of the system equations are first examined.

The introduction of extraneous roots by differentiation is clearly pointed out in the second example of the paper. However, it would be interesting to know if the equations of this example could come directly from a physical system. Also, this set may be shown to require only four arbitrary constants by the fact that it can be reduced to a third-order equation in y with the introduction of only one arbitrary constant in the process of this reduction.

Henry M. Paynter (American Center for Analog Computing, Boston, Mass.) and **Daniel H. Sheingold** (George A. Philbrick Researches, Inc., Boston, Mass.): The authors' use of the matrix approach is to be commended for the ease of scaling, the economy of amplifiers, and the inherent solution stability, all of which are direct consequences of a highly organized and well-thought-out formulation technique. The comprehensive treatment of the subject of redundant integrations and ambiguous solutions is very timely and should be of paramount importance to all those seriously interested in the machine solutions of systems of differential equations.

It is also particularly interesting to note the compact matrix form of the amplifier diagram; one novel feature of the symbolism is the use of conductance measures rather than resistances which results in a direct relationship between coefficients in the equations and physical parameters in the machine. However, we might suggest that a logical advantage could result from placing the feedback conductor in such ideographs in a position analogous to the capacitor whenever an amplifier is used merely as a summer or inverter. It is recognized, nevertheless, that there are perhaps comparable advantages to having all capacitors northwest/southeast and all conductors northeast/southwest.

The principal purpose of this discussion is to show that certain commercially available computers permit direct translation from the original matrix form (and, of course, from the original equations) to machine interconnections and parametric settings. Such machines are composed of modular elements which are called, for convenience, Universal Linear Operators. Fig. 6 shows the front panel of one modular element, and Fig. 7 shows a bank of 12 such elements. The basic equation, which completely describes the performance of each element is

$$e=e_0+10^m p^{-n}\sum_{i=1}^{4} a_i e_i \qquad (40)$$

where

$m=0, 1, 2, 3$

$n=0, 1$

$$1/p=\int_0^t (\ )dt \qquad (41)$$

The signal e_0 is adjustable to any positive or negative constant voltage within the output range of the element in steps of 0.1 volt;

and a_i is adjustable to any positive or negative value from 0 to 11.10 in steps of 0.01 by means of 3-digit decade settings. It is seen immediately that this operator may function either as an integrator ($n=1$) or as a summer ($n=0$), and that the m parameter permits, in effect, a choice among four values of feedback resistance or capacitance. The voltage e_0 then functions either as a directly additive constant in the case of simple summation, or as an initial condition in the case of integration.

The only fundamental distinction affecting problem formulation between the operators described in the foregoing and operational summing points in the authors' matrix diagrams is in the location of the inverting amplifiers. The operational elements described here have outputs which are of one sense only, i.e., "direct," or positive.

The choice of signs is made via a switch at each input. This somewhat simplifies programming formulation because all variables may be defined as positive and be given sensed coefficients where operated upon. Although more than the minimum number of amplifiers might be used for a given problem configuration, the fact that they are inherently available in each operator means that there is, in reality, no "waste" of amplifiers.

We show in Figs. 8 through 10 tabular forms which completely define the computor problem setup including:

1. interconnections
2. parameters
3. initial conditions

and furthermore do so without reference to internal electronic functioning. Thus, individuals without prior knowledge of the nature of analog computing circuitry can successfully set up such programs directly from the matrix equations, and entirely nontechnical personnel can set up and run the machine directly from the tabular forms depicted.

Fig. 8 gives the tabular setup for equation 20 and Fig. 1 (for the homogeneous case). Note that the module numbers correspnd one to one with the problem variables (the columns in the matrix). Note also that when more than four inputs are required as in the second row of equation 20, additional modules can be employed; in this case only one extra module (number *10*) was required.

Figs. 9 and 10 correspond to equations 34 and 38 and Figs. 2 and 3 respectively. Note again that the parameters can be set directly from the matrix itself. Fig. 11 gives solutions of the second example under the initial conditions of equation 29, comparable to those shown in Fig. 4 for x_1, x_2, and x_3. If these three variables and their rates of change must be displayed then six operators must be used. However, if only the variables themselves are required, the minimum number of four operators may be used.

It may be of interest to note that the actual setup time requred by an individual reasonably experienced in the use of the equipment amounted to 4 minutes for equation 20, and 2 minutes apiece for the other two examples. The actual running time for each case being under 1 minute, the total time required for the solution of all three equations was less than 15 minutes.

V. H. Disney (Armour Research Foundation, Chicago, Ill.): The authors have developed a very clear and useful system for the orderly manipulation of the equations to be mechanized on an analog computer. Description of the equations in matrix form permits an easily checked layout of the programming connections which should do much to reduce the possibility of error. It should be noted, however, that only the scales of coefficients and dependent variables are changed by the procedure described. It is suggested that this system be extended to include change of time scale as well. If this were done the question arises as to what order of scale change in time, coefficient, and variable should be made for optimum programming. Guides might be developed for selecting reasonable values of the scale changes.

The authors have also described the difficulties that can arise when equations are differentiated. This is not a widely used technique. I should like to ask the authors if they would recommend avoiding this practice altogether, or whether there are means to test the solutions for validity.

R. E. Horn and P. M. Honnell: We are keenly appreciative of the favorable view of our work expressed by Dr. Pipes, for he is among the handful of mathematically inclined scientists in the entire world who have pioneered and steadfastly pursued researches for almost a quarter of a century in the application of matrix methods to engineering problems. This was long before the electrical engineering profession generally had any cognizance of the existence of these mathematic methods, much less of their application to electical engineering problems.

The writings of Dr. Pipes have, over the years been a source of instruction, guidance, and motivation to all of us who now pursue matric methods in our own specialties of the moment. In particular, we hope to be able to apply the results of the researches of Dr. Pipes, in the difficult area of variable and nonlinear systems, to the electronic computing techniques we describe; needless to say, these are matric methods! It must give Dr. Pipes great satisfactoin to see his prescience so abundantly substantiated.

The comments of Dr. Rideout concerning the application of these methods to systems of nonlinear equations are particularly pertinent. It is in these areas that a large percentage of problems of current interest lie—complex systems of equations in which the systematic matrix approach is particularly helpful. The authors plan to consider these aspects in more detail in their future publications.

With regard to Dr. Rideout's question concerning the origin of the equation in the second example, the basic form of the equation was obtained directly from a system of equations representing an aircraft hydraulic servo system. In the original simulation of this problem, the extraneous linear term was introduced inadvertently using conventional techniques and caused considerable difficulty in the manner that is described in the paper.

With reference to the discussion by Dr. Paynter and Mr. Sheingold the following applies. One of the objectives of the authors' paper was to indicate the application of the matrix approach to existing computers. By presenting such a complete discussion of the application to a particular commercial machine, the discussors have placed additional emphasis on this aspect of the use of matrix methods.

Because of their generality, the matrix programming methods should also aid considerably in obtaining the fullest utilization of other existing computers.

We are glad to have Mr. Disney bring out the question of change-of-time scaling. This is again most concisely stated in terms of premultipliers and postmultipliers. Consider, for example, the change in time scale represented by

$\tau/k=t$ and $f(\tau/k)=f(t)$,

where

t = original independent variable
τ = transformed independent variable
k = constant of proportionality

as applied to equation 22 of reference 3, namely

$$\begin{bmatrix} D & -I & 0 & \ldots & 0 & 0 \\ 0 & D & -I & \ldots & 0 & 0 \\ . & . & . & \ldots & . & . \\ 0 & 0 & 0 & \ldots & D & -I \\ A_1 & A_2 & A_3 & \ldots & A_n & A_{n+1} \end{bmatrix} \begin{bmatrix} x \\ Dx \\ . \\ D^{n-1}x \\ D^n x \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ . \\ 0 \\ f(t) \end{bmatrix}$$

With appropriate premultipliers and postmultipliers (omitted herein), this yields the desired expression

$$\begin{bmatrix} D_\tau & -I & 0 & \ldots & 0 & 0 \\ 0 & D_\tau & -I & \ldots & 0 & 0 \\ . & . & . & \ldots & . & . \\ 0 & 0 & 0 & \ldots & D_\tau & -I \\ A_1 & kA_2 & k^2A_3 & \ldots & k^{n-1}A_n & k^nA_{n+1} \end{bmatrix} \begin{bmatrix} x \\ D_\tau x \\ . \\ D_\tau{}^{n-1}x \\ D_\tau{}^n x \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ . \\ 0 \\ f(\tau/k) \end{bmatrix}$$

wherein

$D_\tau{}^n=I\times d_\tau{}^n$,

$d_\tau{}^n$ is written for $d^n/d\tau^n$, and, of course, $D=(1/k)D_\tau$.

With respect to Mr. Disney's last point, we defer to the mathematicians, who teach that equivalent differential systems can be obtained only if the determinant of the transformation matrices are constant. This permits the appearance of the derivative operator among the elements of transformation matrices, subject to the aforementioned restriction. It does rule out the differentiation of equations per se.

Proposed Standard Terms and Definitions for Magnetic Amplifiers

AIEE COMMITTEE REPORT

THE PURPOSE OF THIS PAPER is to review the present status of terms and definitions in the rapidly expanding magnetic-amplifier field. Since the first progress report of the Magnetic Amplifiers Subcommittee in 1950[1] much effort has been directed towards preparing a list of terms and definitions to supplement and replace those original definitions which were no longer considered adequate.

It should be recognized that the preparation of a list of useful terms and definitions is not a small task. To serve properly the needs of the magnetic-amplifier field, it was necessary to examine a large amount of literature to extract those technical terms referred to, described, and defined. These terms, in addition to many other suggested terms, required careful scrutiny in order to evaluate their suitability.

The project of preparing a group of preferred terms and definitions in a dynamic technical field is hampered to some extent by the dictionary's definitions of "term" and "definition." According to Webster, "term" means a word or expression having a precisely limited meaning or peculiar to a science, art, or the like; as a technical term. The meaning of "definition" is the explanation of the meaning or meanings of a word; also, a formulation of such meaning or meanings.

In a technical field the existence of several meanings of a word may frequently lead to utter confusion; similarly, the existance of several terms to describe some unique or special phenomenon tends to create difficulties.

The problem facing the Definitions Subcommittee of the Magnetic Amplifiers Committee during the last several years has been one of attempting to provide in each case one term and one definition which would be adequate.

During this time, a list of more than 100 terms and definitions have been thoughtfully reviewed and considered, and this progress report is a means of acquainting persons in this field with a partial list of terms and definitions which have been agreed upon by the subcommittee.

As a result of numerous committee meetings, surveys, ballots, and lengthy discussions, there is at this time a group of 38 terms and definitions which the Definitions Subcommittee and the Magnetic Amplifiers Committee have approved. These terms and definitions have been recently reviewed and accepted by the Standards and Test Codes Subcommittee of the Magnetic Amplifiers Committee. This group of terms and definitions has been transmitted to the AIEE Standards Committee with the endorsement of the Magnetic Amplifiers Committee.

In addition to the group of terms and definitions recommended for use is a rather large group of terms and definitions which are being considered for future recommendation. Though the magnetic amplifier is a static device, the activities of the Definitions Subcommittee are truly dynamic.

Proposed Standard Terms and Definitions

The following list contains the proposed standard terms and definitions for magnetic amplifiers:

1. *Bias Windings*—The bias windings of a saturable reactor are those control windings by means of which the operating condition is translated by an arbitrary amount.

2. *Control Windings*—The control windings of a saturable reactor are those windings by means of which control magnetomotive forces are applied to the core.

3. *Feedback* (in a magnetic amplifier)—A circuit connection by means of which an additional magnetomotive force, which is a function of the output quantity, is used to influence the operating condition.

4. *Feedback Windings*—The feedback windings of a saturable reactor are those control windings to which the feedback connections are made.

5. *Magnetic Amplifier*—A device using saturable reactors either alone or in combination with other circuit elements to secure amplification or control.

6. *Output Windings*—The output windings of a saturable reactor are those windings other than feedback associated with the load and through which power is delivered to the load.

7. *Power Windings*—The power windings of a saturable reactor are those windings to which the power is supplied by a local source. Commonly the functions of the output winding and the power windings are accomplished by the same winding, which is then termed the "output winding."

8. *Saturable Reactor*—An electromagnetic device, employing one or more nonlinear magnetic cores; used in a-c circuits to secure amplification or control, commonly by means of a d-c signal which influences the nonlinearity.

9. *Saturating Reactor*—A nonlinear reactor without provision for influencing the nonlinearity.

10. *Self-Saturation*—Self-saturation in a magnetic amplifier refers to the connection of half-wave rectifying circuit elements in series with the output windings of the saturable reactors.

11. *Signal (input, control)*—A signal is an independent input variable. It is applied to the magnetic amplifier as an electrical quantity which controls the output.

12. *Signal Windings*—The signal (input) windings of a saturable reactor are those control windings to which the independent variables (signals) are applied.

13. *Control Ampere-Turns*—Control ampere-turns expresses the magnitude and polarity of the control magnetomotive force required for operation of a magnetic amplifier at a specified output.

14. *Control Characteristic*—The control characteristic of a magnetic amplifier is a curve of the output quantity versus control quantity under specified conditions, both expressed in suitable units.

Paper 58-175, recommended by the Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted November 4, 1957; made available for printing November 13, 1957.

Personnel of the Definitions Subcommittee of the Magnetic Amplifiers Committee: D. Feldman, *chairman*, A. B. Haines, P. W. Barnhart, T. G. Blanchard, V. B. Boros, H. F. Eckbels, L. A. Finzi, A. E. Fitzgerald, W. A. Geyger, A. Krausz, R. C. Lewis, H. W. Lord, R. E. Morgan, P. Siskind, D. H. Smith, H. F. Storm, and G. L. Sullivan. Space does not permit listing the names of the many other persons who have contributed their time and effort to the preparation of this paper: the contributions of past members of the Magnetic Amplifiers Committee and its various subcommittees are gratefully acknowledged.

15. *Cross-Conduction*—Cross conduction in a reversible magnetic amplifier is the simultaneous conduction or gating of half-wave elements connected in a mesh containing the a-c supply voltage but not the load.

16. *Drift*—Drift in a magnetic amplifier is a change in the control characteristic due to unassignable causes over a specified time interval.

17. *Dynamic Coercive Force*—That value of applied magnetomotive force at which a major dynamic hysteresis loop crosses the abcissa axis (has zero value of magnetization).

18. *Dynamic Hysteresis Loop* (*A-C Hysteresis Loop, Flux-Current Loop, Flux-Ampere-Turn Loop*)—The dynamic hysteresis loop of a core is the curve of magnetization versus applied magnetomotive force per unit length obtained when the magnetic material is cyclically magnetized at some specified rate. The magnetization at any instant is the average flux density over the entire core section. The applied magnetomotive force per unit length at any instant is that required to provide the flux and rate of change of flux implicit in the test or operating specifications.

19. *Dynamic Magnetizing Force*—The applied magnetomotive force per unit length required to provide the flux and the rate of change of flux specified by the conditions for which a dynamic hysteresis loop is determined.

20. *Dynamic Permeability*—The permeability determined by the slope of a line joining the tips of a dynamic hysteresis loop under specified conditions.

21. *Firing*—Firing in a magnetic amplifier is the transition from the unsaturated to the saturated state of the saturable reactor during the conducting or gating alternation. Firing is also used as an adjective modifying phase or time to designate when firing (n) occurs.

22. *Ferroresonance* (See also Nonlinear Resonance)—If the dissipation of a passive electric network, containing at least one capacitor and at least one nonlinear inductor, is sufficiently low, the curve of response (e.g., rms value) of the network to an electric driving signal is double-valued over a certain range, when plotted against the independent variable of driving force, or frequency, or one of the network parameters. Such a network is said to be in ferroresonance, if the operating point is on the upper leg of this double-valued response curve, and if the lowest-frequency component of the response is of the same frequency as the fundamental frequency of the driving force.

23. *Ideal Saturable Core*—A core displaying idealized magnetic characteristics, i.e., a magnetization curve represented by two straight lines, having u=zero above the knee and u=infinity below the knee, and having no losses.

24. *Ideal Saturable Reactor*—A saturable reactor employing ideal cores, having perfect electromagnetic coupling among all windings on a common core and characterized by absence of losses and capacitances.

25. *Ideal Transformer*—A transformer employing ideal core or cores operating in the unsaturated region of the core characteristic, having perfect coupling between windings and further characterized by absence of winding resistances, losses, and capacitances.

26. *Impeded Harmonic Operation* (*Constrained Magnetization, Forced Magnetization*)—Impeded harmonic operation denotes that type of operation which takes place in a magnetic amplifier in which the impedance of the control circuit and any circuit closely coupled to it is so great as to substantially prevent the flow of all harmonic currents in such circuits.

27. *Magnetic Flip-Flop*—A bistable circuit employing one or more magnetic amplifiers so arranged as to have two discrete levels of output which may be obtained by adjusting the control voltage or current.

28. *Magnettor*—A second harmonic-type magnetic modulator.

29. *Nominal Control Ampere-Turns*—The difference between the control ampere-turns for minimum output and for rated output is the nominal control ampere-turns difference or, briefly, control ampere-turns.

30. *Nonlinear Resonance* (See also Ferroresonance)—Provided the dissipation of the system is low, the curve of the response (e.g., rms value) to a driving force, of a double energy-storage, passive system containing at least one nonlinear energy storage element, may be double-valued over a certain range, when plotted against the independent variable of driving force, or frequency, or one of the system parameters. Such a system is said to be in nonlinear resonance, if the operating point is on the upper leg of this double-valued response curve, and if the lowest-frequency component of the response is of the same frequency as the fundamental frequency of the driving force. If the circuit parameters or the excitation or both preclude the existence of a double-valued response, the system is said to be in nonlinear resonance if the operating point is in that range of the curve of response (e.g., rms value) versus driving force, in which the slope of the curve is greater than the slope in the vicinity of the origin.

31. *Postfiring*—Postfiring refers to the interval during the gating or output alternation following firing. It is used as an adjective to describe phenomena occuring during this interval.

32. *Prefiring*—Prefiring refers to the interval during the output or gating alternation preceding firing. It is used as an adjective to indicate phenomena occurring during this interval.

33. *Rectifier, Complementary*—Complementary rectifiers are those half-wave rectifying circuit elements in the output circuit of a magnetic amplifier which are not self-saturating rectifiers.

34. *Rectifier, Self-Saturating*—Self-saturating rectifiers are those half-wave rectifying circuit elements connected in series with output windings of a saturable reactor in the self-saturating magnetic amplifier circuit.

35. *Response Time*—The response time of a magnetic amplifier is that period of time required for a given change of the output quantity following a step change of the input quantity. This change of the output quantity shall be 63% of the total change unless otherwise specified. The "response time" specified shall be the maximum which exists for any condition within the rating (e.g., such effects as growth or decay, time phase of signal application, or temperature).

36. *Saturable Transformer*—A saturable reactor in which both output windings and power windings are employed, commonly to secure voltage transformation or circuit isolation from the a-c supply.

37. *Unimpeded Harmonic Operation* (*Natural Magnetization, Free Magnetization*)—Unimpeded harmonic operation denotes that type of operation which takes place in a magnetic amplifier in which the impedance of the control circuit or any circuit closely coupled to it is so small as to permit substantially unimpeded flow of all harmonic currents in such a circuit.

38. *Environmental Sensitivity*—Environmental Sensitivity in a magnetic amplifier is the change in the control char-

acteristic due to specified changes in environmental conditions. These include changes in ambient temperature, supply voltage, supply frequency, and other specified changes.

◆

Discussion

H. F. Storm (General Electric Company, Schenectady, N. Y.): While most of the terms under discussion were in common usage many years ago, a better understanding of magnetic-amplifier function gained since then has led to changes in terminology. In the belief that a proposed standard should reflect present-day terminology, and serve as a guide for future writing rather than as a dictionary of past terms, I have prepared the following comments on some of the terms under consideration. The various terms in the following are identified by the numbers used in the paper.

6. *Output Windings*—This term appears to have been virtually discarded. For instance, at the AIEE–Institute of Radio Engineers Conference on Magnetic Amplifiers in 1957 I did not find a single paper where the term "output windings" was used. Likewise, a check through a recent volume of *Communication and Electronics*,[1] did not reveal a single instance where the term "output windings" was used. My suggestion is that the term be removed from the proposed standard under discussion. As a replacement, "gate windings" is recommended. The use of this term is widespread, and it has the further advantage of conciseness, as will be shown. The terms "gate," "gate circuit," etc., are also well established in other areas such as in connection with electronics and transistors e.g., see references 2 and 3 of this discussion.

As far as the term "gate" in magnetic amplifier work is concerned, its popularity may be gauged from the fact that "gate windings" is used in seven out of the eight magnetic-amplifier papers published in the aforementioned issue of "*Communication and Electronics*,[1] and many other examples could be listed. The spread of this term through industry across the country is indicated by the following representative list of authors of these seven papers, and their affiliations: Andress Kernick, H. A. Perkins, Jr., Westinghouse Electric Corporation, Pittsburgh, Pa.; T. T. Kadota, and H. C. Bourne, University of California, Berkeley, Calif.; W. R. Seegmiller, General Electric Company, Schenectady, N. Y.; E. W. Manteuffel, and R. O. McCary, General Electric Company, Ithaca, N. Y.; Robert M. Hubbard, Boeing Airplane Company, Seattle, Wash., R. J. Distler, and C. Sturzenbecker, Bell Telephone Laboratories, Inc., Whippany, N. J.; and H. C. Bourne, Jr., and D. Nitzan, University of California, Berkeley, Calif. The eighth paper on the subject, by R. A. Raber, does not discuss the "gate windings" and hence no term for these windings appears.

The term "gate windings" is derived from the manner in which these windings function: essentially, they either block current flow or they freely admit current flow. Similar action is encountered in many electronic and transistor circuits; these circuits are called "gate circuits" in the literature.[2,3]

The concisiveness of the term "gate" is still more apparent when it is used in conjunction with other terms. For instance, compare "voltage across the output windings" with the simple "gate voltage."

In view of the foregoing, my recommendation is to replace the presently proposed "output windings" by "gate windings," in accordance with the following definition:

The gate windings of a saturable reactor are those windings, other than feedback windings, which cyclicly permit the flow of load current.

7. *Power Windings*—In the paper, the "power windings" are defined as those". . . to which the power is supplied by a local source." I am at a loss to visualize the meaning and significance of a "local source," and feel that the definition of "power windings" should be suspended until the meaning of "local source" is established. Furthermore, it would be helpful to have described an example for the difference between the terms numbered 6 and 7.

21. *Firing*—Although in quite common usage, the term "firing" has the following drawbacks: first, nothing really fires. Second, the term may mislead the uninitiated reader to assume a tube in use somewhere, an allegation which most magnetic amplifier engineers would rather avoid. My suggestion is to replace "firing" by "saturating," with the following definition:

Saturating in a magnetic amplifier is the transition from the unsaturated to the saturated state of the saturable reactor. Saturating is also used as an adjective modifying phase or time to designate when saturating occurs.

28. *Magnettor*—This term has been used in papers on the subject only once or twice, and I have never heard it used anywhere else. The term should be dropped.

31. *Postfiring*—For reasons similar to those given for item 21, it is recommended that "postfiring" be replaced by "saturating interval."

32. *Prefiring*—For reasons similar to those given for item 21 it is recommended that "prefiring" be replaced by "presaturating."

34. *Rectifier, Self-Saturating*—Although this term is in somewhat common usage, it is cumbersome and perhaps misleading. My suggestion is to call these rectifiers "gate rectifiers," and that they be defined as follows:

Gate rectifiers are those half-wave rectifying circuit elements connected in series with the gate windings of a saturable reactor in the self-saturating magnetic amplifier circuit.

36. *Saturating Transformer*—The definition of this term is based among other things on "power windings." This latter term, however, is in need for clarification (see item 7); hence, the term "saturating transformer" should be held in abeyance pending clarification of item 7.

R. E. Anderson (General Electric Company Schenectady, N. Y.): The standards proposed by the committee should become most helpful in establishing consistent terminology in the magnetic amplifier field and thus aid in the communication and understanding of this technology. This discussion, which will be directed toward items 16 and 38, entitled drift and environmental sensitivity, is intended to cover certain details regarding the nature and effects of these particular items and thus provide insight to the possible uses and implications of the definitions. The definitions are concerned with the changes or shifts which may alter the zero or quiescent point of a magnetic amplifier. Specifically, these shifts, which may be viewed as an axis translation within the amplifier, are those which occur after the amplifier has been zeroed, i.e., adjusted to obtain a suitable quiescent point, or after it has been calibrated. Thus, gain shifts or variations dependent upon signal level are excluded from this discussion. In this way, the phenomena under consideration may be represented by an additional signal

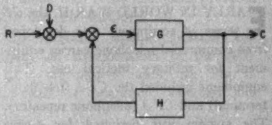

Fig. 1. Amplifier with magnetic feedback

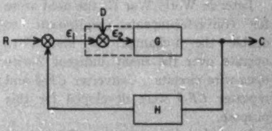

Fig. 2. Amplifier with electric feedback

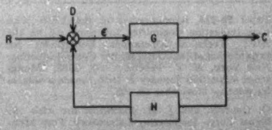

Fig. 3. Amplifier showing equivalent drift

or output of constant magnitude, which may appear in a manner independent of the signal or the loading. In the definition now proposed, we find that two types of zero shift are defined as opposed to one drift suggested by many of the previous standards. For instance, the progress report of the subcommittee[1] has led many of us to consider as drift, changes arising from both environment and unassigned causes.

NOMENCLATURE

C = controlled variable
D = drift input
G = transfer function of forward path
H = transfer function of feedback path
R = reference input signal

By examining the magnetic amplifier in block diagram form, the influence of the variations of the zero point may be examined for either magnetic feedback, Fig. 1, or electric feedback,[2] Fig. 2. That is, when the comparison between the reference and the feedback signal is made by opposing windings on the magnetic core of the amplifier, the zero shift may be introduced as shown in Fig. 1. On the other hand, if the reference and feedback are compared in an electric circuit external to the amplifier, Fig. 2 applies. In this figure, the dashed lines indicate that the drift introduction takes place within the amplifier components, i.e., internal to the amplifier block. In either case, the loop equations yield

$$\frac{C}{R+D}=\frac{G}{1+GH}$$

Thus it may be seen that both cases are equivalent to Fig. 3, where the loop regulates to a point erroneously offset from the reference position by the zero shift amount.

Accordingly, it may be concluded that offset of the zero or changes in the quiescent point introduced a fundamental error in the accuracy of the closed-loop system. This error is somewhat analogous to the resolution errors frequently encountered in mechanical systems. Since these errors are not reduced by increases in loop gain, the errors must be considered as a portion of the system design or application task, regardless of the cause producing the shift. Unfortunately, the nonlinear manner in which the various changes may combine makes it difficult to determine the total shift from information on shifts produced by separate causes.

For these reasons, it would be most helpful to those applying, using, or purchasing magnetic amplifiers to have the supplier indicate the total, i.e., maximum, change or shift in operating point arising from all causes, known or unknown, and especially including, but not restricted to, those changes arising from the anticipated variations of environment. From the foregoing analysis, the importance of distinguishing between quiescent shifts and gain variations becomes apparent. In keeping with current definitions, let me further suggest that it might be well to use the word drift to indicate this maximum quiescent change arising from all causes. Thus, limiting the use of the term "drift" to zero shifts, by excluding gain variations and by including all causes of quiescent change within the one term, should result in a more practical and useful definition.

A Frequency-Converting Telephone Carrier Repeater for Military Use

G. GOLTSOS
NONMEMBER AIEE

J. H. JOHNSTON
NONMEMBER AIEE

R. B. ANDERSON
NONMEMBER AIEE

EARLY IN WORLD WAR II, the *CF* series of equipment was developed from commercial telephone carrier equipment for military tactical use. This equipment included the *CF-1* (telephone terminal) and *CF-3* (telephone repeater). The system was designed for 4-wire operation over the spiral-4 type of cable or radio relay.

Later in World War II, the need arose for converter-repeater equipment to enable the 4-channel *CF* system to operate over the many indigent 2-wire open-wire circuits. Converter *CF-4* and repeater *CF-5* were developed for this purpose.

Since that time, a series of compact, lightweight equipments has been designed specifically to meet the logistic and performance requirements of modern warfare. These equipments include the telephone terminal *AN/TCC-3* and telephone repeater *AN/TCC-5* (a 4-channel carrier system) and the telephone terminal *AN/TCC-7* and telephone repeaters *AN/TCC-8* and *AN/TCC-11* (a 12-channel carrier system).

The design criteria applied to all the equipment of this series were based on the proven technical art existing in the latter phase of the Korean period: aluminum transit cases, shock frames, plug-in chassis components, and vacuum-tube circuitry. Once the basic 4-channel system was designed, the converter-repeater *AN/TCC-6*, described in this paper, followed. Fig. 1 shows the *AN/TCC-6*, which was developed in 1952–1956, and which is more advanced in technical design. This, added to its important role in systems, qualifies the subject for technical release to interested engineering groups.

The equipment has been designed in accordance with the logistic requirement that fewer equipments perform the necessary system functions and that they be smaller and lighter. Converter-repeater *AN/TCC-6* replaces the system function of World War II converter *CF-4* and repeater *CF-5*. It accomplishes this replacement with an accompanying reduction in volume and weight so great that the *AN/TCC-6* might very well be continued as a companion piece with transistorized equipment now in laboratory phase of development. The converter-repeater *AN/TCC-6* weighs 70 pounds and has a volume of 2 cubic feet, as compared to the converter *CF-4* weight of 280 pounds in a volume of 12 cubic feet and the repeater *CF-5* weight of 380 pounds in a volume of 17.7 cubic feet.

Applications

The basic design function of the *AN/TCC-6* is to convert the 4-wire operation

Fig. 3. Block diagram of AN/TCC-6 used as 2-wire repeater

of telephone terminal *AN/TCC-3* and repeater *AN/TCC-5* to 2-wire operation. This is accomplished by translating the 4- to 20-kc base band for one direction of transmission to a 24- to 40-kc band. Thus, at the 2-wire side of the *AN/TCC-6,* the directions of transmission are separated in frequency rather than by two separate wire pairs. When 0.165 copper wire is used, a nominal nonrepeatered circuit length of 310 miles may be obtained. A block diagram of such an installation is shown in Fig. 2.

Two *AN/TCC-6* units may also be connected back to back, to form a 2-wire "frequency-frogging" repeater. By the process of frequency-frogging, the frequency bands for both directions of transmission are transposed and interchanged as they pass from one line section to the next. Fig. 3 illustrates this use in a multirepeatered system.

The technique of frequency-frogging offers two distinct advantages from the standpoint of transmission. As a result of the interchange of frequency bands, individual channels in the band are inverted as to their order in the frequency spectrum. Since attenuation is greater at the higher frequencies, signals subject to more loss in one section are subject to less loss in the next. The overall effect from terminal to terminal is a correction of the slope which would otherwise be present in the frequency-attenuation characteristic curve and, consequently, a uniform loss throughout both bands. In addition, singing and crosstalk between repeaters at the same installation are minimized, since the high-level output of each repeater is at a different frequency from that of the low-level input to itself and other repeaters.

For optimum performance, the number of repeater sections in a system is limited by design objectives to three. However, where some degradation is tolerable, longer systems may be used. Performance within design objectives may be obtained over distances up to 750 miles in a system using three repeater sections and 0.165 copper wire.

The *AN/TCC-6* may also be used with telephone terminal *AN/TCC-3* and radio set *AN/TRC-24* to form an 8-channel radio communication terminal. For this purpose, an *AN/TCC-6* is connected to each of two *AN/TCC-3* terminals and the two *AN/TCC-6* units are then cross-connected to each other.

Fig. 4 illustrates this application. The outgoing 4-channel, 4- to 20-kc band from terminal 2 is translated to a 24- to 40-kc band by one *AN/TCC-6* and then passed to the other *AN/TCC-6* where it is combined with the outgoing 4-channel, 4- to 20-kc band from terminal 1. The resulting 8-channel, 4- to 40-kc band is passed to the *AN/TRC-24* and transmitted. In a similar manner, the incoming 4- to 40-kc band from the *AN/TRC-24* is separated in one *AN/TCC-6* into a 4-channel, 4- to 20-kc band and a 4-channel, 24- to 40-kc band. The 4- to 20-kc band is directed to terminal 2 and the 24- to 40-kc band is passed to the other *AN/TCC-6* where it is translated to a 4- to 20-kc band and directed to terminal 1. Necessary cross connections are made with cords and jacks provided with the *AN/TCC-6.*

To facilitate trouble location and repair, all subassemblies of the *AN/TCC-6* are plug-in units; see Fig. 5. For ease of operation, switches and

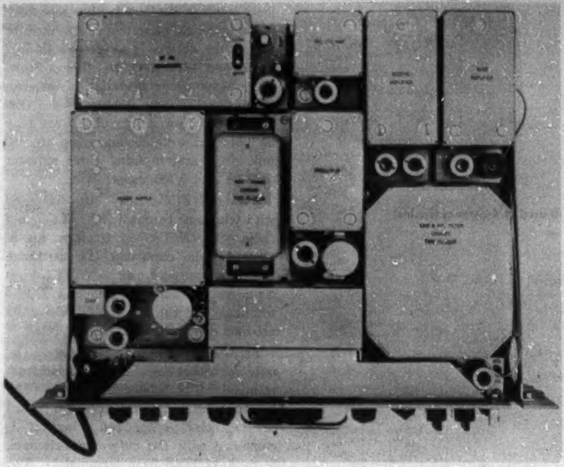

Fig. 5. Top view of AN/TCC-6 showing plug-in construction. The large slotted-head screws keep the plug-in units in place

controls have been kept to a minimum. Miniature electrical components were carefully chosen to meet the severe requirements of high- and low-temperature operation, vibration, shock, and moisture tests.

Consistent with the compact and portable nature of the new requirements for military carrier equipment, the *AN/TCC-6* weighs only 70 pounds and has over-all dimensions of 12 by 17 by 21 inches. The unit is mounted in a waterproof transit case for installation in locations where weatherproof shelter is not available. All controls, lamps, fuses, meters, etc., necessary for equipment lineup, maintenance, and operation are located on the front panel for convenient accessibility.

Operation

The *AN/TCC-6* is designed to operate in either of two options, *A* or *B*, depending on the particular application requirement. In the *A* option, the converter transmits the band from 24 to 40 kc and receives the band from 4 to 20 kc. In the *B* option, the transmitting and receiving frequency bands are interchanged. Block diagrams of the transmitting and receiving signal paths for both options are shown in Figs. 6 and 7.

In operation under the *A* option, the 20-kc generator unit accepts a zero-db (decibel), 4- to 20-kc carrier frequency band and a −25-db, 4-kc alarm pilot from an *AN/TCC-3* terminal. The purpose of the 20-kc generator unit is to provide attenuation control in the base band of 4 to 20 kc and to generate a 20-kc slope pilot from the 4-kc alarm and flat-gain pilot. Controls are provided in the unit for factory adjustment of the pilot level. A terminal/repeater switch is mounted in the top of the unit. When this switch is in the terminal position, the 20-kc pilot is generated for transmission through the system. When the switch is in the repeater position, the local 20-kc generator is disconnected and the 20-kc band elimination filter, *FL101*, is bypassed. Midband output level of this unit is −21 db. The 20-kc pilot is bridged onto the transmitting branch at a level 10 db higher than the 4-kc pilot to provide for relaxation of the 20-kc band elimination filter requirements.

From the 20-kc generator unit, the base band and the 4-kc and 20-kc pilots pass to the modulator-demodulator unit which contains a 20-kc low-pass filter, a modulator (or demodulator), and 20- to 40-kc band-pass filter and a resistive *T* pad. In this unit, the base band of the transmitted frequencies is modulated by a 44-kc carrier and then filtered to derive a lower side band of 24 to 40 kc.

The 44-kc carrier is supplied from a separate plug-in crystal-controlled oscillator unit. This unit consists of an oscillator stage and a buffer amplifier stage which are transformer-coupled. Two controls are provided for factory or repair depot adjustment; a trimmer capacitor for line frequency, and a potentiometer for level control.

When the modulator-demodulator unit is in either of its two positions, the designation *A* or *B*, as appropriate, is readable and a front panel lamp is lighted to indicate the option in use. The total loss of the modulator-demodulator unit is approximately 11 db to produce a level of −32 db at the input to the send amplifier.

The send amplifier provides 49 db of gain to the transmitted band, which results in a level of +17 db per channel at the input of the line and directional filter. The required output level of this amplifier is dictated by maximum line loss of 52 db and also by the minimum allowable receive input level. The two stages of amplification are *5654* and *6005* pentode tubes which are resistance-capacitance coupled. Negative feedback is employed for impedance stabilization and distortion reduction.

The directional and line filter subassembly gives directional separation of transmit and receive carrier frequencies, provides separation of the carrier and order wire circuits, and furnishes a balanced output for connection to the 2-wire line. In *A* operation a 24-kc high-pass filter is connected between the transmitting branch and the 2-wire line. Changing operation to the *B* mode (reversing the modulator-demodulator unit in its socket) changes the connections so that a 20-kc low-pass filter is connected between the transmitting branch and the line. Carrier and order wire circuits are separated at the line by means of a 4-kc high-pass filter and a 3-kc low-pass filter. The output of the 4-kc filter is passed through a transformer which provides a balanced circuit to the line. The 3-kc filter is a balanced configuration which flanks the transformer output. Order wire extension from the *AN/TCC-6* to the terminal equipment is provided by means of auxiliary equipment.

In the receiving direction, carrier frequencies from the line are passed through the directional filter to the receiving gain-adjusting unit, through coaxial connectors. Flat-gain controls consisting of a coarse-gain 20-db-per-step attenuator and a fine-gain 0- to 20-db variable attenuator, provide adjustment for different line conditions. At this point, a preamplifier of 10-db gain

Fig. 7. Block diagram of AN/TCC-6 in B option

raises the level of the received signals to improve operation under conditions of low received signal levels.

Following the preamplifier (*A* option assumed), equalizing networks in the receiving signal path compensate for nonuniform attenuation characteristics of the 2-wire line and of the directional filters. One network is a fixed-slope equalizing filter which is connected in the receiving path only when operation of the *AN/TCC-6* is in the *A* mode. The other networks are a variable slope equalizer and a directional filter equalizer. The output of these equalizers is an essentially flat 4- to 20-kc base band. Under the *B* option, the modulator-demodulator unit (used as a demodulator) is inserted between the preamplifier and equalizing networks.

From the directional filter equalizer network, the received signals pass to a 2-stage receiving amplifier unit which raises the level of received signals to 0 db for transmission to the terminal equipment. The input to this amplifier is at a −61-db level point. The two stages of amplification are *5654* pentode tubes which are resistance-capacitance coupled. As in the send amplifier, negative feedback is derived from a bridge configuration which combines voltage and current feedback in the proper relationship to stabilize the output impedance to about 600 ohms.

"In-service" alignment of the *AN/TCC-6* for various line conditions is performed by metering the 4- and 20-kc pilots which are continuously transmitted. The pilots are bridged off the receive drop terminals, passed through narrow-band filters, amplified, and then rectified and impressed across the db meter mounted on the front panel. The flat gain and slope controls are adjusted to provide a 0-db reading on the meter at the 4- and 20-kc positions of the measure switch.

The power supply is a plug-in unit which provides 6.3 volts a-c for filament heating and 150 and 200 volts d-c for *B*-plus in the active circuits. The unit is designed to operate satisfactorily from 115 or 230 volts a-c (±10%) at 50 or 60 cycles per second (±3 cycles).

Conclusions

A new converter-repeater has been developed for use with existing military telephone carrier equipment. Designated "Converter-Repeater *AN/TCC-6*," this new unit converts either telephone terminal *AN/TCC-3* or telephone repeater *AN/TCC-5* from 4-wire operation over spiral-four cable to 2-wire operation over open-wire lines. In its repeater application, two *AN/TCC-6* units are connected back to back to form a 2-wire frequency-frogging repeater. The new unit may also be used with telephone terminal *AN/TCC-3* and radio set *AN/TRC-24* to provide an 8-channel radio terminal.

Converter-repeater *AN/TCC-6* incorporates improvements in transmission performance and reductions in weight and volume which are marked advantages over military converter-repeater equipment in previous use.

Binary Symmetric Decision Feedback Systems

BERNARD HARRIS
NONMEMBER AIEE

K. C. MORGAN
NONMEMBER AIEE

Synopsis: In a simple binary decision feedback system the receiver, as a result of a decision process made on each received message, either accepts and prints the corresponding symbol, or rejects the message as too ambiguous and reports the rejection to the sender. The information in the ambiguous message is discarded, and the sender subsequently repeats the message. This process permits a trade-off between information rate and error probability.

Schemes are considered here in which the decision process is made on coded word groups as well as on a digit-by-digit basis. The decision processes considered are those based on single-parity-check redundancy as well as on null zones at the receiver. In the particular case of null-zone reception of uncoded digits both the information rate and the error probability may be improved over those of a conventional, uncoded, unidirectional, bilevel system.

General expressions are derived for the information rate and error probability of these systems when the feedback process is error-free. Specific examples are calculated for the case in which the direct-channel interference is additive gaussian noise.

THE ADVANTAGE of a feedback system over a one-way communication link may be illustrated by considering ordinary telephone communication. With a unidirectional link the sender is never quite sure whether any or all of his message is being received. With a bidirectional link the receiver may not only attempt to inform the sender that reception is taking place, but may also attempt to describe the degree of clarity of the reception, thus permitting the sender to adjust his rate and style of transmission appropriately.

Feedback systems may be divided into two classes, according to the type of communication carried by the feedback channel. In decision feedback the receiver decides whether or not the received message can be properly interpreted and then reports its decision back to the transmitter. In information feedback the receiver reports back, in whole or in part, the received information, and the transmitter decides whether or not the receiver has properly interpreted the message.

Once a decision is made that the message cannot be interpreted, the transmitter may repeat, in whole or in part, the ambiguous message, using the same code, or by agreement the system may shift to a higher redundancy code, or both may occur. A separate classification of feedback systems may thus be made by dis-

---

Paper 57-1041, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 7–11, 1957, and re-presented for discussion at the Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted August 9, 1957; made available for printing January 14, 1958.

Bernard Harris and K. C. Morgan are with New York University, New York, N. Y.

The research reported in this paper was performed at New York University under the sponsorship of the Electronics Research Directorate, Air Force Cambridge Research Center, Air Research and Development Command, Laurence G. Hanscom Field, Bedford, Mass., the Air Force Cambridge Research Center, and the Air Research and Development Command, Baltimore, Md., under Contract *AF 19(604)-1049*.

tinguishing between fixed-code systems and variable-code systems.

The advantage of a variable-code feedback system is that the redundancy of the code may be efficiently matched to the interference. This permits the setting of an upper limit on the probability of error, whereas for a unidirectional link the redundancy must be chosen such that the error probability will not be excessive at the poorest signal-to-noise ratio which is anticipated.

General Decision Feedback

In the general decision feedback system an attempt is made to transmit a member of the set of messages, x_i, by transmitting initially the corresponding member from the set of symbols, x_{1i}. If the received message indicates with an acceptable error probability that a particular member of x_i originated the transmission, the received message is so interpreted and the transmitter is correspondingly informed. The transmitter then proceeds with the next message.

When, on the other hand, the received message is considered ambiguous, the transmitter, upon being so informed, replies with the corresponding symbol from the set x_{2i}. In a similar manner, if the information contained in the two received messages is sufficient to permit a decision, the process is terminated and the next message transmitted. If the reception is still insufficient to permit a decision, the corresponding symbol from the next set, x_{3i}, is transmitted, and the process is repeated.

In an attempt to send a single message x_i, therefore, the sender will transmit, as demanded by the receiver, the corresponding set of symbols $x_{1i}, x_{2i}, \ldots$. The process will be terminated only when the receiver indicates that the total information received is sufficient to permit a decision to be made with a specified reliability.

The simplest fixed-code arrangement consists of adjusting the system for best operation at high signal-to-noise ratios, where the probability of requiring corrective information is small. The corrective information may then be poorly encoded without excessive reduction in efficiency by employing simple repetition, and the information which is contained in the rejected message may correspondingly be discarded.

The decision to accept or reject a message is, in general, based on some scheme for distinguishing those points in sample space closely associated with specific message points from those points which are too ambiguous. Such a scheme, for example, may utilize one of the various error-detecting codes.

The general coding problem is, then, to choose, for a given code length, such message words, out of all possible words, that the chosen words are at least $2k+1$ from each other. Under these conditions more than k errors per word must occur before one message is misinterpreted as another, and hence the system is capable of detecting up to k errors. Although this problem has been studied in great detail by many authors, and systematic coding schemes evolved, the general problem remains unsolved.

An alternate decision scheme may be based on the use of null zones[1] at the detector. In its simplest form this technique establishes such a zone at the receiver that the reception of signals within this zone indicates the a posteriori probabilities of the two transmitted states are too nearly equal to permit interpretation without error. The receiver then requests a repeat of this ambiguous information.

This type of reception may be extended to code words by noting that the interpretation of some of the received digits of the code words as nulls constitutes the recognition of additional points in the sample space of the received words at half-unit distances from the conventional binary code points. Such a half-unit point, if sufficiently close to a particular message word, may be interpreted as arising from that word. Otherwise, the received word is considered ambiguous, and the entire word is repeated. Such a system, because of the multilevel nature of its reception, is capable of being adjusted to improve the information rate of the system.[1] In fact, this scheme may be used, even without feedback, to improve the information rate, provided the amount of ambiguous information is not excessive.

When the feedback channel is error-free, the information rate and the error probability of the direct transmission channel remain unaltered if the feedback loop is opened. The important advantage of the feedback loop is that the entire message is eventually received at the specified error probability.

Double-null reception, which bisects the null zone and thereby retains polarity information, permits points in the sample space of the received words between those of the single-null system. This scheme is thus capable of further improving the information rate over single-null reception. However, single-null reception has been shown, under certain conditions, to be capable of achieving about one half of the improvement in information rate theoretically attainable by increasing the number of receiver levels without limit. Double-null reception is capable of achieving only a small improvement over the single null. One advantage of the double-null scheme, however, is the comparative insensitivity to the adjustment of the null level.

In the most elementary form of decision feedback a yes-no reply is fed back for each message sequence in the direct channel. Considerably less feedback capacity is actually required, however, if coding is introduced into the feedback channel. The more precisely the probability of rejection is known, the more efficient this coding can be.

Thus, if a yes-no reply is fed back after each sequence, 2^N distinct sequences of replies may occur, where N is the number of direct-channel sequences in the message. In the limiting case of large N the number of rejections is closely given by uN, where u is the probability of a direct-channel sequence being rejected. By waiting until the end of the message and coding the positions of the uN rejections, only

$$\frac{N!}{(uN)!(N-uN)!} \tag{1}$$

distinct possible replies are required. Since N is large, this requires a return-channel capacity of only

$$-u\log_2 u-(1-u)\log_2(1-u) \tag{2}$$

bits per message sequence in the direct channel.

When the rejection probability is small, coding thus permits great reductions in the return-channel capacity. When the rejection probability is one half, the return channel must carry one bit per direct-channel sequence, and for noiseless feedback the coded and uncoded cases become identical. For rejection probabilities greater than one half the accepted positions instead of the rejected positions should be encoded, and a symmetrical situation exists.

For Uncoded Binary Symmetric Transmission: Single-Null Reception

Consider a general binary symmetric channel where the two input levels x_1 and x_2 are transmitted with equal a priori probabilities. With a 3-level decoder the received signal is assigned to one of three groups:

$$\begin{array}{ll} \text{Group I} & y \geq h \\ \text{Group II} & -h < y < h \\ \text{Group III} & y \leq -h \end{array} \tag{3}$$

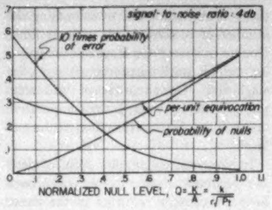

Fig. 1. Variation of parameters of decision feedback system using single-null reception of uncoded binary pulses

Group I records as x_1, Group III records as x_2, and group II records as O.

Because of the symmetry of the system, and presuming amplitude symmetry of the noise, the information rate is bits per symbol is

$$R(k)=p(\mathrm{I}/x_1)\log_2\frac{2p(\mathrm{I}/x_1)}{p(\mathrm{I}/x_1)+p(\mathrm{III}/x_1)}+ p(\mathrm{III}/x_1)\log_2\frac{2p(\mathrm{III}/x_1)}{p(\mathrm{I}/x_1)+p(\mathrm{III}/x_1)} \quad (4)$$

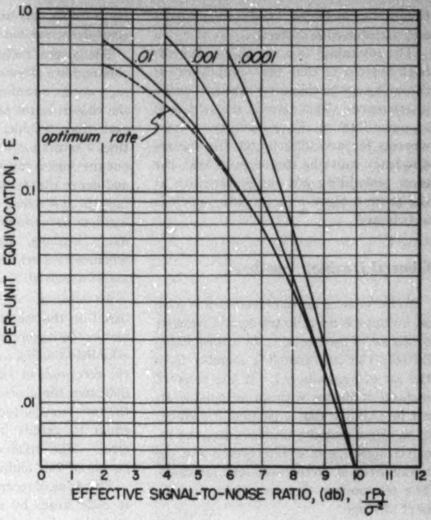
This information rate will in general be greater than that attainable by simple bilevel reception. With a unidirectional system this increase in rate is achieved at the cost of receiving parts of the message as ambiguous. With a feedback link the ambiguous portions of the message may be repeated as often as necessary until properly received. In the particular case of an error-free feedback channel this improvement in information rate may be maintained while the entire message is received at some specified reliability. The error probability of the received message is then

$$P_e=\frac{p(\mathrm{I}/x_1)}{p(\mathrm{I}/x_1)+p(\mathrm{III}/x_1)} \quad (5)$$

Subject only to the reasonable constraint that $p(\mathrm{I}/x_1)$ exceed $p(\mathrm{III}/x_1)$ it may be shown that, when the noise is additive-symmetrical, the rate attains its maximum at some $k>0$. This is shown by noting that dR/dk is positive at $k=0$. In a similar manner it may be readily shown that P_e also attains its best value at some $k>0$. Hence it is always possible to find some setting of the null level at which both the rate and error probability are improved.

To determine the degree of improvement requires that a specific type of interference be considered. For simplicity the interference will again be considered to be additive gaussian noise. A binary symmetric channel is assumed in which there are r transmitted samples per bit of information. When the interference is additive gaussian and is uncorrelated at the sampling points, each received r-group with the same summed amplitude has the same a posteriori probability, and thus can be identified with a single effective received level z.

Fig. 2. Per-unit equivocation versus signal-to-noise ratio for uncoded binary decision feedback system with single null adjusted for a given probability of error. Direct-channel interference is additive gaussian noise. Feedback channel error-free



When the null-zone boundaries are $\pm k$, a normalized signal amplitude A and a normalized boundary K may be conveniently defined as

$$A=\left(\frac{rP_t}{2\sigma^2}\right)1/2$$

$$\text{and } K=\frac{k}{\sqrt{(2\sigma^2 r)}}$$

where P_t is the signal power and σ^2 the noise power.

$$p(\mathrm{I}/x_1)=1/2[1+\phi(A-K)] \quad (6)$$

$$p(\mathrm{III}/x_1)=1/2[1-\phi(A+K)]$$

where $\phi(x)$ is the error function

$$\phi(x)=\frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}dx$$

The analytic expression for the per-message-symbol rate for single-null reception may then be found from relation 4.

Fig. 1 shows the corresponding manner in which the per-unit equivocation and the error probability of the accepted message vary as the null level is raised. The subsequent improvements are, of course, the result of the presence of the feedback channel, which fills in the rejected portions of the message. The degree of activity of the feedback channel is shown by the probability-of-nulls relation in Fig. 1.

Fig. 2 shows the extent by which the rate will vary when the feedback system is adjusted for operation at a given error probability. It should be noted that, for a sufficiently high signal-to-noise ratio and a fixed error probability, the reception reduces to that of a single-null system at the optimum rate. This optimum rate is, of course, better than that of unidirectional bilevel transmission.

For example, at a signal-to-noise ratio of 6 db (decibels), the unidirectional bilevel system has an information rate of 0.84 and an error probability of 0.06. The feedback system, adjusted for optimum rate, has an information rate which is about 4% better and an error probability which is 0.01. By the introduction of a sufficiently high null level the error probability may be reduced tenfold to 0.001 with a corresponding rate reduction of about 10%. To reduce the error probability a hundredfold to 0.0001 would require a rate reduction of 40%.

To examine the nature of this exchange between error probability and information rate, consider the system at low signal-to-noise ratios. The information rate then approaches

$$R \doteq \frac{2}{\pi \ln 2}\left[\frac{\epsilon^{-2K^2}}{1-\phi(K)}\right]^2 \tag{7}$$

and the optimum rate adjustment becomes

$$R \doteq 1.17A^2 \tag{8}$$

Unfortunately the corresponding error probability is excessively high, at 0.50.

If the null level is adjusted for a low probability of error instead of for the optimum rate, the rate relation simplifies to

$$R \doteq \frac{2KA^2}{\sqrt{\pi}\ln 2}\epsilon^{-K^2} \tag{9}$$

and the error probability to

$$P_e \doteq \frac{\epsilon^{-(A+K)^2}}{2(A+K)\sqrt{\pi}} \tag{10}$$

whence R and P_e are related by

$$R \doteq \frac{2A^2P_e}{\ln 2}\left(\frac{-\ln P_e}{\pi}\right)^{1/2} \tag{11}$$

This relation shows that, at low signal-to-noise ratios and at low error probabilities, the information rate is roughly proportional to the error probability.

At high signal-to-noise ratios the rate reduction is considerably less. Unfortunately the relation between error probability and per-unit equivocation is not as simple.

Thus

$$E \doteq \frac{\epsilon^{-(A-K)^2}}{2(A-K)\sqrt{\pi}} \tag{12}$$

while

$$P_e \doteq \frac{\epsilon^{-(A+K)^2}}{2(A+K)\sqrt{\pi}} \tag{13}$$

These relations show, as might be expected, that at high signal-to-noise ratios multifold improvement in the error probability may be obtained with only a small change in the null level. While the per-unit equivocation will correspondingly show multifold increase, the information rate will remain approximately constant as long as the absolute value of the per-unit equivocation is low. This phenomenon is characteristic of most coding schemes, namely, that the schemes operate best when the signal-to-noise ratio is reasonably high.

Hamming Single-Error-Detecting Decision Feedback

SINGLE-NULL RECEPTION

Binary transmissions are usually concerned not with individual pulses, but rather with groups of pulses representing the symbols of a particular alphabet. It is therefore important to perform an analysis based on n-digit pulse groups or words, where the per-unit equivocation and the error probability are based on whether or not the entire words as entities are properly interpreted and recorded. It should be noted that for languages having interword constraints the analysis would necessarily be based on sequences of words as entities.

Consider a Hamming[2] code of m message digits, plus a single additional digit for parity check, being used in a decision feedback system employing single-null reception. The feedback channel is, as before, error-free. Normally the presence of the extra digit permits the detection of an odd number of errors.

The registration of single nulls permits the single parity check to be used, not only for single-error detecting, but substantially for single-error correcting as well. Thus, if a single digit of the $(m+1)$ digits is registered as a null, the parity check is used to fill in the null, and the resultant word is printed. When two or more nulls are received, the word is not printed. When none of the digits are nulls, the word is printed if and only if parity checks.

The symbols q, p, and u are defined as the probabilities that the word is printed correctly, printed incorrectly, or not printed respectively. These are related by

$$q+p+u=1 \tag{14}$$

Similarly, q_0, p_0, and u_0 represent the corresponding single-digit probabilities of being correct, incorrect, or receiving a null. In the presence of additive gaussian noise having a flat spectrum these become

$$\begin{aligned} q_0 &= \frac{1}{2}[1+\phi(A-K)] \\ p_0 &= \frac{1}{2}[1-\phi(A+K)] \\ u_0 &= \frac{1}{2}[\phi(A+K)-\phi(A-K)] \end{aligned} \tag{15}$$

Assume that all permutations of the m message digits are included in the group of words or alphabet which may be sent. Let Q_r represent the probability

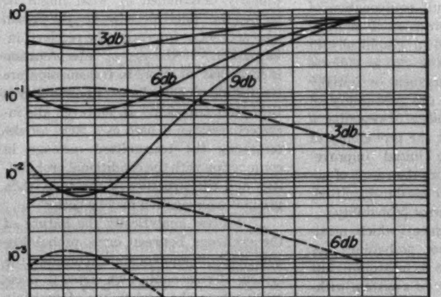


Fig. 3 (left). Per-unit equivocation and probability of error of accepted message for various signal-to-noise ratios and null levels for 5-message-digit, single-parity-check, binary decision feedback system using single-null reception. Direct channel interference is additive gaussian noise. Feedback channel error-free.

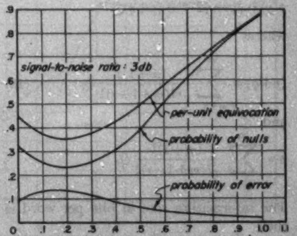

Fig. 4 (right). Variations of parameters of decision feedback system using single-null reception and 5-message-digit, single-parity-check, binary transmission as null level is varied

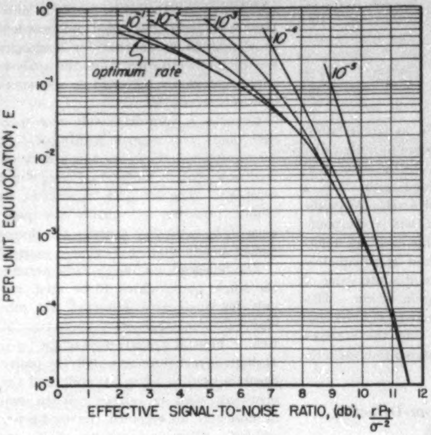

Fig. 5. Per-unit equivocation versus signal-to-noise ratio for a 5-message-digit, plus single-parity-check binary decision feedback system with single null adjusted at values above optimum for a given probability of error. Direct-channel interference is additive gaussian noise. Feedback channel error-free

that a transmitted word will be accepted as another word r units away. Since this requires the misinterpretation of an even number of digits, r is even. If no nulls are received, this misinterpretation can occur only when r errors are made. A misinterpretation may also occur, when one null is received, if r additional errors are made plus a correct interpretation of the null or if $(r-1)$ errors are made, plus an incorrect interpretation of the null. Therefore

$$Q_r = q_0^{m+1-r} p_0^r + (m+1-r) q_0^{m-r} u_0 p_0^r + r q_0^{m+1-r} u_0 p_0^{r-1} \qquad (16)$$

The corresponding number of words r units away from the transmitted word is

$$\frac{(m+1)!}{r!(m+1-r)!} \qquad (17)$$

When the input messages are equally probable and the noise is symmetrical, the output messages are also equally probable, and

$$p(x) = 2^{-m}$$

$$p(y) = (1-u)2^{-m} = (p+q)2^{-m}$$

where

$$(p+q) = \sum_{r=0,2,\ldots}^{m} \frac{(m+1)!}{r!(m+1-r)!} Q_r \qquad (18)$$

and

$$p = \sum_{r=2,4,\ldots}^{m} \frac{(m+1)!}{r!(m+1-r)!} Q_r$$

The information rate in bits per word is then

$$R = m(p+q) - (p+q) \log_2 (p+q) + \qquad (19)$$

$$\sum_{r=0,2,\ldots}^{m} \frac{(m+1)!}{r!(m+1-r)!} Qr \log_2 Qr$$

while the corresponding error probability is given by

$$p_e = \frac{p}{(p+q)} \qquad (20)$$

The relation between the error probability and the per-unit equivocation of this system, in the presence of additive gaussian noise, is shown graphically in Figs. 3, 4, and 5. The curves indicate that as the null adjustment is initially increased from zero, the probability of nulls, i.e., the probability of rejecting a word, decreases, while the probability of error increases. The initial improvement in rate is therefore the result of accepting more words per word transmitted, albeit with increased error probability.

At the null adjustment which maximizes the rate the error probability has already passed through its maximum, but is still poorer than that of a system without nulls. When the null level is adjusted to approximately twice its optimum value, the per-unit equivocation of the system with nulls about equals that of the system without nulls. The corresponding probabilities of nulls are also about equal, but the error probability is now smaller. This means that when the null level is adjusted for the same rate as the system without nulls, about the same number of words are accepted per repeat, but the error probability of the accepted words is smaller.

By adjustment of the null level for a value above the optimum rate adjustment it is possible to exchange information rate for error probability over wide limits. Below the optimum rate adjustment such an exchange is also possible, but not on as efficient a basis.

Consider the system at a signal-to-noise ratio of about 6 db. Without nulls the per-unit equivocation is about 0.1, while the error probability is 0.005. By introducing null reception and maximizing the rate, the rate is improved by about 5% while the error probability is increased 20%. However, if the null system is adjusted for the same rate as the system without nulls, the error probability is decreased by 20%. Adjusting the null level to values above the optimum rate adjustment can result in a fivefold reduction in error probability, i.e., to 0.001, at the cost of 70% rate reduction.

It is significant to note that here is an example of a system which, on the basis of per-unit equivocation, is better, at the optimum rate adjustment, than conventional binary reception, but which, on the basis of error probability, is worse. The reason is that error probability and per-unit equivocation are not uniquely related to each other. Specifically, the error probability is the same whether only one incorrect word or many different words can be received per transmitted word. The relative value of per-unit equivocation and error probability is ultimately determined by what might be termed the "final" decoder, i.e., the person who acts on or interprets the received information. If the act or interpretation is such that all errors in transmission are treated identically, the error probability is the better criterion. If, however, the incorrect message is used as a basis for determining the transmitted message in conjunction with the conditional probabilities and the structure of the code, then per-unit equivocation may be better.

To express analytically the nature of the exchange between error probability and per-unit equivocation, consider the system at reasonably high signal-to-noise ratios where the probability of multiple errors or multiple null digits per word is small. It may be shown that the information rate approaches

$$R \doteq mQ_0 = mq \qquad (21)$$

while the error probability becomes

$$P_e \doteq \frac{m(m+1)Q_2}{2} \qquad (22)$$

From relation 21 it may be established that operating the system at the optimum rate adjustment causes an improvement in the signal-to-noise ratio equivalent to

1.4 db when compared with the system without null reception on the basis of rate. As previously shown, however, the error probability at this optimum rate adjustment is poorer. In fact, at high signal-to-noise ratios, and at the optimum rate adjustment

$$-\ln P_e \doteq 3 \ln u_0$$

or

$$-\ln P_e \doteq 2.06A^2 \tag{23}$$

This is in contrast to simple binary reception where, at high signal-to-noise ratios

$$-\ln P_e = 2A^2 \tag{24}$$

The corresponding deterioration in the error probability is equivalent to a loss of 0.26 db in power, whereas the increase in rate is equivalent to a 1.4-db increase in power.

The behavior of the null adjustment which maximizes the error probability may be determined by examining the system at high signal-to-noise ratios, where

$$P_e \doteq \frac{m(m+1)Q_2}{2} \tag{25}$$

Since

$$Q_2 \doteq p_0^2 + 2u_0p_0 \tag{26}$$

the consequent relation is

$$-\frac{u_0'}{p_0'} = 1 + \frac{u_0}{p_0} \tag{27}$$

For additive gaussian noise this reduces to

$$\exp(4AK) \doteq \frac{\phi(A+K) - \phi(A-K)}{1 - \phi(A+K)} \tag{28}$$

or in the limit

$$A^2 \doteq -\frac{\ln Q}{4Q} \tag{29}$$

This latter relation shows that, as the signal-to-noise ratio increases, the null level at which the error probability achieves its maximum decreases to zero. This is in contrast with the adjustment for maximum rate, wherein the normalized null level Q approaches 17.2% in the limit. The comparison confirms the observation that at a given signal-to-noise ratio, as the null level is raised, the error probability achieves its maximum before the rate is maximized. Hence, best operation is obtained for null adjustments greater than that required to optimize rate.

There remains to examine the condition of adjustment at which the system with nulls has the same rate as conventional reception. It is noted that, at high signal-to-noise ratios, adjustments of the null above the optimum rate adjustment correspond to u_0^2 being greater than p_0. Since, with null reception

$$E = (m=+1)p_0 + \frac{m(m+1)}{2}u_0^2 + \dots \tag{30}$$

then, at high signal-to-noise ratios, above the optimum rate adjustment

$$E \doteq \frac{m(m+1)}{2}u_0^2 \tag{31}$$

The condition for this adjustment may consequently be shown to reduce to

$$A^2 \doteq 2(A-K)^2 \tag{32}$$

or

$$Q \doteq 1 - \frac{\sqrt{2}}{2} = 29.3\% \tag{33}$$

By adjusting the null level to 29.3% of the effective signal-to-noise ratio, in the presence of additive gaussian noise, the rate of the system with nulls will be nearly equal to the rate of a system employing conventional reception.

It is of interest to compare the probability of rejecting a word for these two systems. Simply by noting that, for this adjustment

$$(1-Q_0) >> Q_2 >> Q_4 \dots \tag{34}$$

it follows that, at high signal levels

$$u \doteq 1 - Q_0 \tag{35}$$

and also

$$E \doteq 1 - Q_0 \tag{36}$$

Thus, at high signal-to-noise ratios, the equivocation is primarily dependent on the rate of rejection rather than the distribution of error.

It is interesting to compare the relations for error probability of the feedback systems with and without null reception. Without nulls

$$-\ln P_e \doteq 2A^2 \tag{37}$$

whereas, with nulls

$$-\ln P_e \doteq (5 - 2\sqrt{2})A^2 \tag{38}$$

when the rates are adjusted to be equal. The introduction of null reception has improved the error probability by an equivalent 0.35-db increase in power. The nulls are thus performing error-correction.

The behavior of this system at low signal-to-noise ratios may be improved, as may all systems, by the introduction of a variable code. Consider, for example, that the system, at low signal-to-noise ratios, is to be modified so that each digit is repeated several times by the sender and correspondingly integrated before decoding. For noise which is uncorrelated with the signal, this results in an effective improvement in the signal-to-noise ratio, but causes a corresponding decrease in rate. The optimum arrangement, from the viewpoint of best rate, is shown in Fig. 6. For example, below a signal-to-noise ratio of about 3 db, an error probability of 0.01 can be maintained at a higher information rate by a system which employs single repetition. Below about 0.5 db, double repetition is better. At still lower signal-to-noise ratios additional repetitions are desirable.

One of the main advantages of the feedback system over a unidirectional system is that this altering of the redundancy of the code can be done as the interference level changes. Hence the higher redundancy required at low signal-to-noise ratios need not reduce the information rate at high levels.

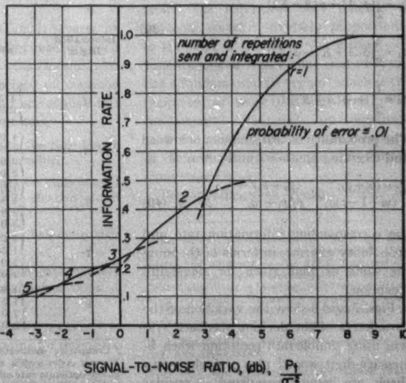

Fig. 6. Information rate versus signal-to-noise for a variable-code, 5-message-digit, single-parity-check, binary decision feedback system. Direct-channel interference is additive gaussian. Feedback channel error-free

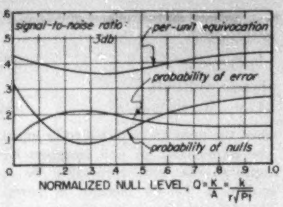

Fig. 7. Variations of parameters of decision feedback system using double-null reception and 5-message-digit, single-parity-check, binary transmission as null level is varied

DOUBLE-NULL RECEPTION

With double-null reception the interpretation of the received signal is identical to that of single-null reception except when multiple nulls are being received. Then, instead of always being rejected, the word is rejected only if parity does not check the digits indicated by the polarities of the nulls. With such a decoder the probability of error cannot be continuously reduced by increasing the null level, since very high null levels reduce the system to simple binary reception. One advantage of this system, however, is that the information rate for any setting of the null adjustment is better than that of a system without nulls.

As before, let q_0 and p_0 represent the probabilities of receiving correct and incorrect digits respectively, while q_1 and p_1 represent the probabilities of receiving the corresponding nulls. In the presence of additive gaussian noise

$$
\begin{aligned}
q_0&=\frac{1}{2}[1+\phi(A-K)]\\
q_1&=\frac{1}{2}[\phi(A)-\phi(A-K)]\\
p_1&=\frac{1}{2}[\phi(A+K)-\phi(A)]\\
p_0&=\frac{1}{2}[1-\phi(A+K)]
\end{aligned}
\tag{39}
$$

The probability of transmitting one word and receiving another r units away is

$$
\begin{aligned}
Q_r=&(q_0+q_1)^{m+1-r}(p_0+p_1)^r+\\
&(m+1-r)q_0^{m-r}p_0^rp_1+rq_0^{m+1-r}p_0^{r-1}q_1
\end{aligned}
\tag{40}
$$

the corresponding information rate and probability of error, in terms of Q_r, being the same as that given for single-null reception.

Figs. 7 and 8 show the variation of the parameters of the decision feedback system using double-null reception when 5-message-digit words, plus a single parity check, are being transmitted. Consider Fig. 7 where the variation is shown for a 3-db additive gaussian noise signal-to-noise ratio. The effect of introducing the null level is to reduce the probability of nulls, but to increase the probability of error. This means that more words are accepted without being repeated, but the probability of error of the accepted words is greater. However, for a fixed signal-to-noise ratio, the range of variation of both the per-unit equivocation and the probability of error is limited. This is in contrast with uncoded single-null reception where, by the introduction of the null, both the per-unit equivocation and the probability of error are improved, and it is also in contrast with a single-parity-check, coded, single-null reception system where, by varying the null level, the rate may be indefinitely exchanged for probability of error.

To express analytically the nature of this exchange, consider the system at a high signal-to-noise ratio where the probability of multiple error digits or multiple nulls per word are small. Then

$$Q_0>>Q_2>>Q_4\ldots \tag{41}$$

The information rate, as for single-null reception, then approaches

$$R\doteq mQ_0 \tag{42}$$

while the probability of error of the accepted digits becomes

$$P_e\doteq\frac{m(m+1)}{2}Q_2 \tag{43}$$

Thus for double-null reception, as for single-null, the procedure of maximizing the rate may be approximated by maximizing the Q_0 or q.[1] Differentiating the expression for q yields, at high signal-to-noise ratios

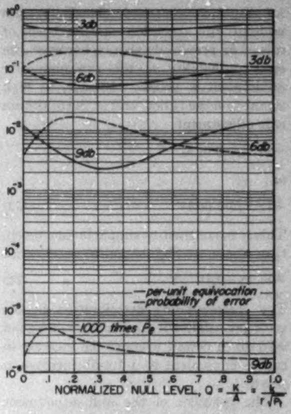

Fig. 8. Per-unit equivocation and probability of error at accepted message for various signal-to-noise ratios and null levels for a 5-message-digit, single-parity-check, binary decision feedback system using double-null reception. Direct-channel interference is additive gaussian noise. Feedback channel error-free

$$\frac{q_0'}{p_1'}=\frac{-q_0}{mp_1} \tag{44}$$

or, in the presence of additive gaussian noise

$$\exp(4AK)\doteq\frac{1+\phi(A-K)}{m[\phi(A+K)-\phi(A)]} \tag{45}$$

This relation for the optimum null

* Comparing undirectional systems employing no coding, Hamming single-error-correcting codes, or Wagner codes with a decision feedback system using a single-parity-check code and single-null reception at the optimum rate adjustment.

† This is identical to the α in Table III of reference 3.

level is not the same as that for the single-null system. In particular, at high signal-to-noise ratios, the expression reduces to

$$e^{4AK} = \frac{2A\sqrt{\pi}}{m} e^{A^2} \tag{46}$$

For large A, since the exponents predominate, this reduces to

$$Q = \frac{K}{A} = \frac{1}{4} \tag{47}$$

To understand better the effect of this choice of null level, note that the optimum adjustment approximately corresponds to adjusting p_0 to be equal to the product of q_1p_1. Based on this adjustment the per-unit equivocation becomes

$$E \doteq (m+1)(p_0 + mq_1p_1) \tag{48}$$

or

$$-\ln E \doteq \frac{25}{16} A^2$$

Based on per-unit equivocation, the introduction of the double null can, therefore, yield an equivalent improvement of 1.9 db over the system without nulls, and a 0.5-db improvement over single-null reception. The corresponding probability of error of the accepted message at the maximum rate adjustment is, however, somewhat poorer than for the system without nulls. The difference in error probabilities, decibelwise, vanishes at large signal-to-noise ratios.

Compared to Unidirectional Systems Which Use Error-Correcting Codes

It is of interest to compare the performance of the single-null decision feedback system with unidirectional systems which use error-correcting codes. The schemes chosen for comparison are those tabulated by Silverman and Balser.[3] These are: 1. an uncoded m-digit word transmission; 2. a single-error-correcting code using the minimum number of parity checks; and 3. an m-digit Wagner code. The feedback code chosen for comparison is the Hamming single-parity-check code of m information digits. The null level will be considered to be adjusted for optimum rate.

Table I reproduces the foregoing information, adding the data for the feedback system. These systems are compared on the basis of the same noise-free rates. It should be noted that, because of the rejection feature, the actual time required to transmit a message using the decision feedback system is greater than that required by the undirectional systems by a factor equal to the reciprocal of $(1-u)$. This corresponds, over the range of m in this table, to an increase of from 23% to 40% for $A=1$ and from 4% to 8% for $A=1.5$. For greater signal-to-noise ratios the time devoted to repetition becomes negligible. The tabulation emphasizes the reduction in error probability which may be achieved by using decision feedback for error correction.

It is seen therefore that, where a return channel is already available, or where the need for reliability justifies the additional cost of establishing such a channel, the decision-feedback approach offers a relatively simple and practicable means of achieving a substantial error reduction.

A Constant-Amplitude Random Function Generator

G. A. HELLWARTH
NONMEMBER AIEE

THE constant-amplitude random function generator described in this report resulted from the need for an electronic generator which would combine some of the properties of random noise waveshapes with the known characteristics of periodic, constant-amplitude waves. In this instance, a wave shape was desired which had as a main feature a constant peak-to-peak amplitude, but whose path between peaks was in some way randomly chosen.

At first inspection the simplest way to generate such a function would be that of amplitude clipping any noise-like wave shape. However, this was thought to be unsatisfactory because the wave spends too much time at the peak value, or clipping level, rather than traversing between peaks. The next criterion on the wave shape, then, was that it reverse its direction immediately after reaching each peak.

There appeared to be several common wave shapes that would accomplish this task. The most obvious were:

1. A sawtooth wave with the time length of its tooth randomly determined.
2. A triangular wave with the time lengths of both the positive and negative slopes randomly chosen.
3. A cosine wave with its half-cycle time length randomly chosen.
4. A wave with a random path between peaks, each path maintaining a slope of constant sign.

At this point, it becomes necessary to define some standard terms for discussion of the proposed wave shape.

Given a constant-amplitude wave shape, a single excursion of the wave between two peaks shall be called a "side." The time derivative or slope of a side is a constant for a sawtooth or triangle wave. A side of a cosine wave shall be the value of the cosine function between 0 and π, or π and 2π. The side time-length, or "side time," is defined as the time duration of a side's excursion from one peak to the next. The side time of a triangle or sawtooth wave is inversely proportional to the slope of the side. A constant side time triangle or cosine wave (not random) has a fundamental frequency which is the reciprocal of twice the side time. The fundamental frequency or repetition rate of a sawtooth wave is the reciprocal of the side time, assuming a zero flyback time; see Fig. 1.

Perhaps the most evident reason for

Paper 58-533, recommended by the AIEE Electronic and High Frequency Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Great Lakes District Meeting, East Lansing, Mich., May 5–7, 1958. Manuscript submitted January 27, 1958; made available for printing February 25, 1958.

the introduction of this terminology is that the functions will actually be generated by randomly choosing each side time-length, resulting in the description of the wave being a probability distribution of side times. In practice, however, it was found to be much easier to measure the power spectrum than the side-time distribution, so both frames of reference will necessarily be used.

The Random Sawtooth Generator

General Description of Operation

The first type of random wave shape generated was the sawtooth, primarily because this type of generator was thought to be the simplest to design and build. The generator was to operate at audio frequencies and was to have as much flexibility as possible in controlling its side time-length distribution. The random sawtooth block diagram is shown in Fig. 2, and a schematic circuit diagram is shown in Fig. 3. Essentially, the generator consists of a Gaussian noise source being sampled at the time of the sawtooth flyback, the noise sample being held and integrated until the output reaches some constant value. At this point the integrator is reset, causing the sawtooth flyback, and a new noise sample is taken and integrated, etc. The integrator is a constant-current pentode discharging a capacitor, resetting being due to a thyratron recharging the capacitor. The noise samples are capacitor-coupled into the pentode grid, a controllable grid bias determining the center side time; the center side time is that side time resulting from a zero noise sample; see equation 4.

Integrator Operation

A simplified integrator circuit, as shown in Fig. 4, is helpful in observing the generator operation during the formation of a single side.

The current sources in Fig. 4 represent a pentode whose only plate load is a capacitor C. Thus, during the length of time required to generate one side, a constant current is being fed into the capacitor to produce the ramp function of voltage across the capacitor. If g_m is the transconductance of the pentode, $I_o=g_mE_o$ is the pentode current resulting from the grid bias voltage E_o, and $I_n=g_mE_n$ is the pentode current resulting from the noise sample voltage E_n, then the capacitor voltage $E(t)$ will be

$$E(t)=\frac{I_o+I_n}{C}\,t=\frac{g_m(E_o+E_n)}{C}\,t,\quad 0\leq t\leq T \tag{1}$$

And since (E_o+E_n) is constant during a side, the time length of the side is that time T, required for the capacitor voltage to change by E_m volts, the peak-to-peak voltage of the sawtooth wave. Therefore

$$T=\frac{CE_m}{g_m(E_o+E_n)}=\frac{CE_m}{I_o+I_n} \tag{2}$$

Thus, equation 2 gives the relation between the sample of noise E_n, and the side time T, produced by such a noise sample. The effect of varying the pentode grid bias E_o can also be seen. A quantity to note in equation 2 is the transconductance g_m, which in practical cases is never a constant, but is a function of E_n. By choosing differing types of pentodes in the generator circuit, one is able to obtain different relations between E_n and T according to the particular way a pentode transconductance varies with its input. Another tool available for controlling the side time T, produced by a noise sample E_n, is the nonlinear amplitude attenuating filter, which can be inserted between the noise source and the sampling circuit. This type of network will effectively introduce to equation 2 a nonlinear factor, a monotonic function of E_o, which multiplies E_o.

The circuit described in Fig. 3 contains a sharp cut-off pentode and no amplitude attenuating network. Amplitude attenuating filters are discussed in greater detail in a later section.

Discussion of Laboratory Model

The random sawtooth circuit is relatively stable and reliable. The most critical element appears to be the pentode, since its d-c characteristics are used to determine the center side time. However, the output power spectrum is not seriously affected by slight changes in the pentode characteristics. A limit can be set on the maximum time length of any side by simply paralleling the integrating capacitor with a suitable resistance so that if the pentode were cut off by a large noise sample, the resistor would discharge the capacitor at a predetermined exponential decay rate.

The center side time is controllable between 0.2 and 10 milliseconds by varying the pentode grid bias. Maximum deviations of side time from the center depend on the pentode grid bias setting, but 200 to 1 maximum to minimum side-time ratios are achievable with the pentode grid bias near the middle of its range. A much more satisfactory way of changing the center side time would be to vary the size of the integrating capacitor, always

leaving the grid bias in the middle of its range. This would yield a side-time distribution which does not vary with the center side-time setting.

LIMITATIONS OF THE SAWTOOTH WAVE SHAPE

The output power spectrum of the random sawtooth is very wide and contains a considerable band above audio frequencies. (There are no spectrum or side-time curves in Appendix I for the sawtooth, since it became only a forerunner of the more significant triangle and cosine generator.) The higher frequency spectral power, caused chiefly by the rapid flyback of the sawtooth, requires a correspondingly wide bandwidth for any associated circuit to pass the wave and maintain its constant-amplitude character. It was then decided to try to generate one or more of the other waves described in Fig. 1, waves which would not have the large amount of high-frequency power resulting from discontinuities. In the triangle and cosine waves, the power spectrum was expected to be much more concentrated in the range corresponding to the side-time distribution, resulting also in increased ability to control the output power spectrum.

The Random Triangle, Cosine, and Square Wave Generator

DESIGN CONSIDERATIONS

In planning the design of a random triangle generator, there were several problems of circuit choice and complexity that were not encountered in the sawtooth generator. The basic block diagram of the circuit, as shown in Fig. 5, is similar to the diagram of the sawtooth, but the contents of the blocks are quite different.

The first design consideration resulted in choosing an operational-amplifier integrator circuit which could integrate positive and negative inputs. The output of the integrator operates between constant peak-to-peak limits by the action of the amplitude discriminator circuit. When the integrator output reaches a certain magnitude, i.e., the preset peak value, the bistable discriminator circuit is "flipped," resulting in a trigger pulse to the sampler and a reversal of polarity of the integrator input signal. This action takes place at both positive and negative peaks, thus confining the integrator output between the peak values. The output to the integrator is the sum of two signals, (1) the constant-amplitude square-wave output of the amplitude discriminator E_o, and (2) the random-amplitude square-wave output of the noise sampling and holding circuit E_n. The operation of the circuit is wholly dependent upon the successful generation of the integrator input signal.

Analysis of Generator Operation

RELATION BETWEEN INTEGRATOR INPUT AND OUTPUT SIDE TIME

Given an integrator circuit as shown in Fig. 6(A), an equation of operation similar to equation 1 can be written. The time T required for E to change by E_m volts is given by equation 3, since (E_o+E_n) is constant throughout the interval T.

$$T=RC\frac{E_m}{E_o+E_n} \tag{3}$$

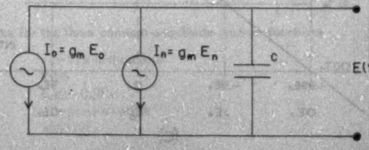
The "center" side time T_o is again defined as that side time generated when the noise voltage sample E_n is zero.

$$T_o\triangleq RC\frac{E_m}{E_o} \tag{4}$$

Fig. 6(B) shows the expected ramp function of voltage versus time obtained at the integrator output, when a constant is integrated. The differing times required for the output to change by E_m volts when the input is varied is indicated by the three sides pictured. Fig. 6(C) is a quasi-log-log plot of equation 3.

INTEGRATOR INPUT REQUIREMENTS

The first requirement to be noted is that at every proposed peak of the integrator output, the polarity of the integrator input signal (E_o+E_n) must be reversed. The signal E_o, which is a positive constant, is intended to produce the necessary changes of polarity at the integrator input by alternately appearing as $+E_o$ or $-E_o$. However, in order that



$I_o = g_m E_o$
$I_n = g_m E_n$

the total input signal change polarity as dictated by the sign of E_o, then equation 5 must hold:

$$E_n > -E_o \text{ when } +E_o \text{ is integrated} \quad (5)$$
$$E_n < E_o \text{ when } -E_o \text{ is integrated}$$

If side times shorter than $1/2(T_o)$ are to be desired, then there must be two separate sources of noise signal E_n from which the integrator receives its input. One source shall be defined as E_n+, and it will provide the input noise signal in conjunction with $+E_o$; the second source, E_n-, will provide the input with $-E_o$.

The dual noise shaper takes a single noise voltage input e_s, and feeds this signal through two parallel shaping amplifiers (or attenuators) whose characteristics are opposite in polarity. These two shaped signals are then alternately sampled and held yielding E_n+ and E_n-, respectively. The output versus input amplitude characteristic of the shaper circuit is arbitrary, as long as the clipping levels maintain the limits on e_n as indicated in Fig. 7. A relatively simple shaper characteristic was chosen for this generator: a fixed gain for noise signals of the same polarity as E_o, and a smaller, variable gain for signals opposite in polarity to E_o; the ratio of these two gains is designated as the shaper gain ratio R. The amplitude characteristics of the two channels of the shaper circuit are alike except for polarity, as shown in Fig. 7.

CALCULATION OF SIDE-TIME PROBABILITY DENSITY

If the amplitude probability density $p(e_s)$ of the noise signal e_s is known and the shaping circuit characteristic is chosen, the side-time probability density can be calculated; that is, the probability that the output wave is being generated with a side time within some finite range

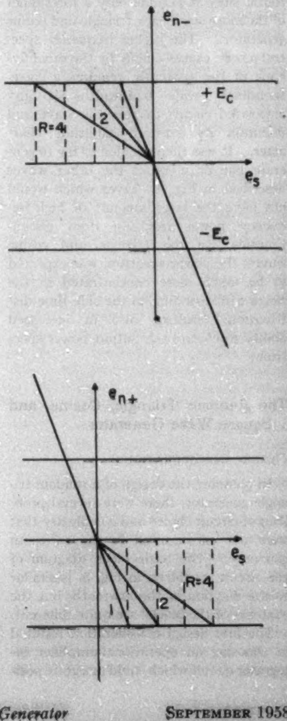

Fig. 7 (right). Dual noise shaper characteristics. Plot of output e_n versus input voltage e_s for different gain ratios R with a fixed clipping level E_c

of values. Since the shaping characteristic is a nonlinear function, as shown in Fig. 7, any calculation will have to be done piecewise with each linear portion of the shaper characteristic.

In general, the amplitude probability density of the shaped noise $p(e_n)$ is found by

$$p(e_n) = p(e_s)\frac{de_s}{de_n} \tag{6}$$

where the derivative is calculated from the shaping characteristic. From equation 4 the side time T, resulting from a sample E_n of the shaped noise voltage e_n, is given by

$$T = \frac{T_oE_o}{E_o + E_n} \tag{7}$$

The probability density of choices of side time $q(T)$ made by the circuit as it samples e_n for each choice, is then calculated as

$$q(T) = p(E_n)\frac{dE_n}{dT} \tag{8}$$

where $p(E_n)$ is assumed equal to $p(e_n)$ and the derivative dE_n/dT is found from equation 7:

$$\frac{dE_n}{dT} = \frac{d}{dT}\left(\frac{T_oE_o}{T} - E_o\right) = -\frac{T_oE_o}{T^2} \tag{9}$$

Since each side time chosen by the circuit occupies a portion of time equal to T, the output side-time probability density $r(T)$ is found by weighting the $q(T)$ density with the factor T:

$$\begin{aligned} r(T) &= \frac{T}{T_a}q(T) = \frac{T}{T_a}p(E_n)\frac{dE_n}{dT} \\ &= \frac{T}{T_a}p(e_s)\frac{de_s}{de_n}\frac{dE_n}{dT} \\ &= \frac{T_oE_o}{T_aT}p(e_s)\frac{de_s}{de_n} \end{aligned} \tag{10}$$

where T_a is a constant used to maintain unity area under the $r(T)$ curve. Thus equation 10 shows the method for calculating the side-time probability density of the output constant-amplitude random function.

EXPERIMENTAL DETERMINATION OF THE OUTPUT POWER SPECTRUM

It would be desirable to know the relationship between the side-time probability density, $r(T)$ (previously determined), and the output power spectrum. Much time was spent in an attempt to relate these two functions, but without success. However, in spite of the advantages of having the mathematical equation, some practical insight into this relationship can be derived experimentally. When the noise signal e_s is gaussian noise, the measured power spectrum for a cosine

output, as shown in Fig. 8, consists primarily of two relatively straight roll-offs from the center frequency $f_o = 1/2(T_o)$. It would then seem necessary only to relate these roll-offs with the amplitude of the side-time density on either side of T_o. Unfortunately, the constructed laboratory generator was not built to provide easy measurement of the noise rms voltage σ, the clipping level E_c, and the shaper gain ratio R. Also, the accuracies of the shaping, sampling, and hold circuits are not sufficient to guarantee a high degree of reproducibility of settings. Approximate values are stated, however, on the power spectrum measurements shown.

Fig. 9 shows power spectra for the three constant-amplitude random functions which the generator produces (i.e., the square wave, the triangle wave, and the cosine wave). Very little difference in the power spectra is noted between the triangle and cosine waves.

General Circuit Discussion

COMMENTS

The laboratory generator was designed and constructed as an experimental piece of equipment. Consequently, there are many potentiometers built in for adjusting parameters in the various parts of the circuit, most of the controls being either for gain or for d-c bias.

Perhaps the major problem encountered in the design and construction of the constant-amplitude random function generator was insuring that the input to the integrator reversed polarity at the end of each side. In the circuit developed, this was done, as mentioned previously, in the noise-shaping circuit by the clipping diodes. Since the noise wave form in each channel of the shaping circuit is unbalanced, the shaping, sampling and hold circuitry must be direct-coupled in order to preserve the direct voltage level corresponding to the average value of the noise voltage before shaping. This requires that the two channels hold their direct potentials, with respect to each other, or the clipping levels E_c will vary; the tolerances on E_c are fairly small if the side times as large or greater than 10 T_o are desired. Another problem in feeding the generator input properly is whether or not to capacitor-couple the output of the hold-circuit to the integrator input. A large capacitor was used in the circuit, but it is suspected that the small currents flowing through this coupling capacitor are sufficient to disturb the capacitor potential, since these currents are random.

A recommendation would be that the clipping level E_c be accomplished at the integrator input (see Appendix II) so that the circuit could more effectively guarantee reversal of polarity after each side. If the application of this function generator does not demand that the clipping level E_c be more nearly equal in amplitude to E_o than about $-0.8\,E_o$, then the present circuit will operate reliably; in other words, this generator will easily produce side times five times as long as T_o (the center side time), but the probability that the integrator input polarity will not reverse after every side increases as one attempts to set the clipping level closer to $-E_o$ and obtain longer side times in the output. When the input polarity does not reverse after a side, the output will pass out of the constant peak-to-peak region and take about 0.1 second before the circuit resumes proper operation.

CIRCUIT DIAGRAM

Fig. 10 shows the circuit of the laboratory model of the constant-amplitude random function generator. Fig. 11 shows the cosine shaper and power supply. A general discussion of the circuit operation is given in more detail in Appendix I, while a transistorized generator is discussed in Appendix II.

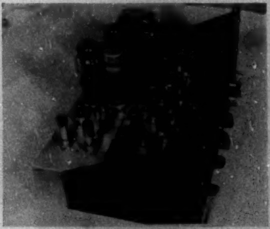

Fig. 14. Laboratory generator

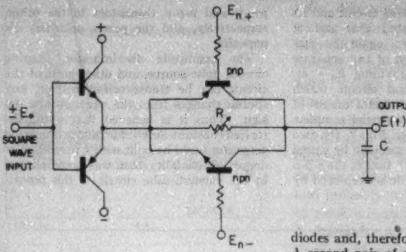

Fig. 15. Transistorized integrator

OSCILLOGRAPHS OF OUTPUT WAVE

Several photographs of an oscilloscope displaying the output wave shape versus time are included, each one a time exposure of many sweeps of the oscilloscope with each sweep beginning at a peak of the wave. Fig. 12 shows the three output modes running at steady state; that is, without any noise voltage. Fig. 13(A) shows three views of the triangle wave using different sweep rates on the oscilloscope; Fig. 13(B) shows three similar views of the cosine wave. In these illustrations the side time distributions can be observed with respect to statistical variations in the choices of side times, the wide range of chosen side times, and the apparently continuous representation of side times when a large number of oscilloscope traces are recorded. Fig. 13(C) and 13(D) differ from the foregoing in that fewer traces are pictured in order to show statistical variations; all of these samples are at the same oscilloscope sweep speed.

Fig. 14 shows the laboratory model with self-contained, regulated power supply.

Appendix I. Detailed Circuit Operation of the Function Generator

The noise source e_s is a *6D4* gas triode (*V*1) operating as a diode in a magnetic field; see circuit of Figs. 10 and 11. In order that the instantaneous noise voltage remain relatively constant during the 10-μsec (microsecond) sampling gate, the noise is bandwidth-limited by a single *RC* low-pass filter with a time constant of about 40 μsec. That is,

$$BW = \frac{10^6}{(2\pi)\,(40)} = 4{,}000 \text{ cps}$$

The filtered noise is then fed through a gain control (*P*-9) and amplified (*V*2) before being put into the dual shaping circuit.

The dual shaping circuit consists of four back-biased diodes. Two diodes (*1N39A*) effect the hard clipping of the noise, one diode in each channel, while a potentiometer (*P*-2) controls the bias on these diodes and, therefore, the clipping level E_c. A second pair of diodes (*1N34A*), each in series with a variable resistance, attenuates the instantaneous signals of the same polarity, in each channel, as those being clipped. A dual potentiometer (*P*-1) controls the amount of attenuation, thus controlling the shaper gain ratio.

The dual sampling circuit is made as follows: Two parallel triodes (*V*3) are operating with a common plate resistor in a normally cut-off state. The shaped noise voltage is direct-coupled to the grids of the triodes, but the grid bias is controlled by two cathode followers (*V*4). When a sample is taken, a 10-μsec pulse is applied to the grid of one of the cathode followers, thus driving the corresponding grid of a sampling triode upward by a fixed amount plus an amount determined by the noise signal. With this arrangement, then, the two shaped noise signals are alternately sampled and fed out at the same point. When the grid biases are properly adjusted (*P*-3, *P*-4) on the sampling triodes, the plate (*TP*-3) will have 100-volt 10-μsec negative pulses appearing.

The voltage on the negative peaks of the sample is fed to the holding capacitor (200 *pf*) through a diode (*V*8), while another diode and pulse generator (*V*7, *V*8) sweep the holding capacitor voltage up to meet the level of the new sample, if the previously held sample was below the new sample. The trigger pulses for both the sampling tubes and the holding capacitor sweeping circuit are obtained by differentiating the two square wave outputs of the amplitude discriminator.

The amplitude discriminator circuit (*V*6) is a bistable multivibrator with a large amount of hysteresis, such that if the input is direct-coupled the multivibrator will flip into one state when the input rises to some specified value, and flop into the other state when the input decays to a second specified value. In this manner, the output of the integrator is contained within constant peak-to-peak limits, since it is the square wave output E_o of the amplitude discriminator circuit which is being integrated. (Of the two out-of-phase square waves available, only one is of the proper phase to be fed to the integrator. Similarly, proper arrangement of the pulses triggering the dual sampler is necessary.)

A potentiometer (*P*-5) controls the effective amplitude of the sampled and held noise compared to the constant amplitude square wave E_o as the two signals are added and power amplified by a cathode follower (*V*10*B*). The center side time T_o is controlled by varying the resistor (*P*-10) at the integrator input. If a large change in T_o is desired, the feedback capacitor (500 *pf*) should be changed. The minimum side time this circuit will generate is about 50×10^{-6} seconds, being limited by responses of the amplifiers.

The integrator operational amplifier (*V*5) contains an internal-positive-feedback loop adjusted by a potentiometer (*P*-12) until a minimum voltage appears at the input grid of the integrator. Two front panel switches are provided. The first (*S*-1) is a function selector, giving either the triangle, cosine, or square wave mode at the output terminals. The second switch (*S*-2) is an output attenuator, the upper position giving a maximum output of about 100 volts, peak-to-peak, while the lower switch position yields about 4 volts. A potentiometer (*P*-11) continuously controls the output level.

The cosine shaping circuit consists of biased diodes arranged to attenuate gradually the peaks of a fixed amplitude triangle wave. Adjustment of the circuit is made by a potentiometer (*P*-8) controlling the input triangle amplitude and a potentiometer (*P*-7) adjusting the level of hard clipping at the wave shape peaks.

Appendix II. Suggestions for a Transistorized Generator

Since the construction of the random function generator, the author has observed some advantages that transistors offer over vacuum tubes in implementing the circuit ideas of this generator. Some qualitative suggestions for transistorized circuitry will briefly be shown in this Appendix, along with the operational advantages which can be achieved. In general, the use of complementary symmetry with transistors enables the design of circuits balanced about ground potential in a push-pull, class *B* fashion.

An integrator is easily made by connecting a capacitor to the collectors of two transistors in parallel, one a p-n-p and the other an n-p-n, as shown in Fig. 15. In this configuration, one of the high-output impedance transistors will feed a current into the capacitor for integration of signals of one polarity, while the other transistor will be used to draw a current from the capacitor for integration of signals of the opposite polarity. The most attractive feature of this integrator for use in the function generator is obtained from the nature of the transistors and the integrator input arrangement, which is such that the input polarity can be reversed after each side with certainty, no matter what amplitude of noise signal is being integrated, as mentioned previously.

The input to the emitters is the square wave output of an amplitude discriminator sensing the integrator output $E(t)$; see Fig. 5. When the square wave is positive, the noise sample E_n+ will determine the constant current flowing in the capacitor, while E_n- should be equal to $+E_o$ during this time in order for the current through the n-p-n transistor to be negligible and to have the same polarity as the current through the p-n-p transistor. Should the amplifier providing the noise sample E_n+ present a sample more positive than E_o, the transistor becomes a perfect clipper in that such a noise sample cannot possibly deliver a current of the wrong polarity to the integrating capacitor. Conversely, during integration of $-E_0$ and its corresponding noise sample E_n-, E_n+ should always be equal to $-E_0$. The resistor R determines the longest side time that can be produced. Note that the output peak amplitude will necessarily be less than E_0.

In view of the previous discussion, the noise sampling circuit need only to provide a shaped noise signal with no clipping, thus eliminating any exacting requirements on the accuracy of the sampling circuit and its amplifiers. It is suggested that use of complementary symmetry again be employed in the construction of two separate sampling circuits, one providing E_n- alternately with the second circuit which supplies E_n+. Since the useful ranges of output voltage of these two noise samplers differ only in polarity, see Fig. 7, the two sampling circuits would especially be suited by complementary design; that is, the n-p-n and p-n-p transistors in one are replaced by p-n-p and n-p-n transistors in the other, respectively, and the power polarities are opposite.

The amplitude discriminator, shaping circuit, noise source, and other parts of the circuit can be transistorized without any special changes from the vacuum-tube design. Thus it is believed that a transistorized constant-amplitude random-function generator could be built with a much higher degree of reliability than was accomplished in the vacuum-tube circuit of this report.

Current-Balancing Reactors for Semiconductor Rectifiers

I. K. DORTORT
MEMBER AIEE

THE ADVANTAGES of the semiconductor diodes in certain applications of d-c power have led to the design and construction of rectifier units of very high current ratings, employing many diodes in parallel on each phase of the rectifier transformer. As with mercury-arc rectifiers with more than one anode connected to each phase, the designer is faced with the problem of current unbalance between parallel elements.

Although the major causes for current unbalance in the two types of rectifiers are quite different from each other, balancing reactors will serve in either case to force proper current distribution. While these reactors resemble each other physically, their modes of operation are different. Moreover, the large number of semiconductor diodes often connected in parallel will generally dictate a different arrangement. It is felt that a brief description of the operation of balancing reactor with mercury-arc rectifiers will be useful as a preliminary to the main subject of this paper.

Anode-Balancing Reactors

In any well designed and properly maintained mercury-arc rectifier, the arc-drop characteristics of the individual anodes are so nearly alike that artificial means of absorbing the voltage difference between them is seldom required. The resistance and inductance of symmetrically arranged anode leads, the flux produced in the iron anode shaft and in the tank wall or anode shield are sufficient to maintain good current balance once it has been established in any conduction period. However, the ignition voltage required to start the arc is often considerably higher than the arc drop needed to sustain the peak current during the rest of the conduction period. Since the two anodes are tied together, the first one to fire will pull down the voltage of the parallel, connected anode to a point below its ignition voltage, and may prevent it from picking up at all during the rest of the cycle. Two parallel anodes will not pick up simultaneously except by rare coincidence. Other disturbing factors may exist, such as the erratic behavior of ignitors in ignitron rectifiers.

In any case, conduction of an anode does not take place immediately after the commutating voltage becomes positive, but some finite time later as at a in Fig. 1, when the ignition voltage E_{pf1} is reached. The anode-to-cathode voltage then drops sharply to the normal arc drop, the difference between the anode and commutating voltage being taken up by the commutating reactance, as indicated by the total, crossed area.

If two anodes are paralleled through a center-tapped anode reactor, a proportional part of the reactance drop occurs across that half of the reactor connected to the anode which picked up first, raising the voltage of the center tap above the anode by that amount. The same voltage appears across the other half of the reactor, raising the voltage of the idle anode above the conducting anode by the full voltage of the reactor. When the full reactor voltage attains the difference between the ignition voltage of the idle anode and the arc drop of the conducting anode, the second anode will fire.

Fig. 1(B) illustrates the current-balancing action of the anode reactor. The curved line i_c represents the commutation current build up of the incoming phase, if conduction starts at the voltage transition point. It is not affected by the number of anodes firing, as long as the commutating impedance is not materially changed. When firing is delayed, for whatever reason, the current build up follows the same curve, shifted downward, parallel to itself, so that it starts at zero. This is illustrated by the heavy portion of curve i_c' in Fig. 1(B).

When the second anode is forced to fire at time b, there is some change of impedance, since the balancing reactor is effectively short-circuited. When the change is small, both anode currents will follow curves parallel to $i_c/2$, displaced so that their sum will always be equal to i_c'. Both anode currents continue to rise to the end of the commutating period or angle of overlap u, at which time the preceding phase current has dropped to zero and the new phase carries the total load current of the commutating group.

From time b until the end of u the two anode currents rise parallel to each other, and then maintain their difference substantially constant, to the end of the conduction period. The maximum difference to be allowed under adverse conditions determines the latest time b when the second anode must pick up.

The reactor must be designed to produce the excess voltage $E_{pf2}-E'_{a1}$ on anode 2 no later than point b in the cycle. The cross-hatched area represents the minimum volt-seconds that must be built into the reactor. However, no additional volt-seconds are required beyond b, except as design margin. For the rest of the

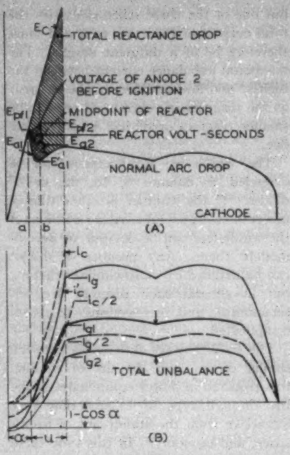

Fig. 1. A—Voltage relationships on mercury-arc anode balancing reactor; E_{pf1}, ignition voltage of anode 1 at time a; E_{a1}, arc drop of anode 1; E_{a1}', arc-drop of anode 1 at time b when anode 2 picks up; E_{pf2}, ignition voltage of anode 2; E_{a2}, arc drop of anode 2. B—Current division in anode reactor; I_c, total commutating current with no delay $=(\sqrt{2}\ E_s/2X_c)(1-\cos \omega t)$; I_c', total commutating current with first anode delayed angle α, $=(\sqrt{2}\ E_s/2X_c)(\cos \alpha-\cos \omega t)$; I_g, total load current on both anodes; I_{g1}, load current on anode 1; I_{g2}, load current on anode 2; α, angle of delay of anode 1 for all causes; u, angle of overlap

conduction period the two anodes are at almost the same potential, and the balancing reactor serves no further purpose.

This principle can be extended to the design of reactors for paralleling three, or even four, anodes. Such rectifiers have been built in the past, but modern practice limits the number of parallel anodes to two. The balancing reactor is therefore a relatively simple device.

Semiconductor Rectifiers

In contrast to the mercury arc, a semiconductor diode has nothing which corresponds to the ignition voltage. Appreciable conduction begins at a relatively low threshold voltage, but, as can be seen in Fig. 2, the current-voltage curve quickly becomes very steep. These curves were drawn for a particular type and class of diodes, and much steeper characteristics have been observed. Because of this steepness, even a few millivolts' difference between two diodes operating at the same current may mean a large difference of current when they operate in parallel, and therefore at the same voltage. This is clearly demonstrated by the equal-current and equal-voltage lines in Fig. 2.

Although some surprisingly heavy current diodes have been produced, the current ratings of large rectifiers require, and probably will require for some time to come, a considerable number of diodes in parallel. Although the number depends on the ratings of cells and the rating of the complete rectifier, as many as 20 or more diodes in parallel may be required. Larger diodes undoubtedly will be developed and produced economically some day, but it is expected that the problem of paralleling will exist for a long time.

In the application of heavy-current selenium rectifiers for plating and similar applications, it has not been uncommon practice to provide a ballast resistor in series with each stack, primarily to prevent a new replacement stack from hogging the load and destroying itself. The use of germanium and silicon rectifiers in the field of power makes necessary a re-examination of the paralleling problem and a re-evaluation of the solutions available. The treatment of these has been varied and ranges from completely natural current distribution to forced current balancing of high accuracy. The following list, with annotations, offers a quick review of the methods used, their merits and limitations.

1. *Natural current distribution.* Only effective to any reasonable extent when several diodes are connected in series, and the series strings are paralleled. Statistical variation offers some balancing effect, depending on the number of diodes in series. Unbalance tends to worsen with increasing load and temperature.

2. *Forward-drop matching.* Use of matched diodes requires careful coding, and replacement of diodes with new diodes in the same code group. Characteristics matched at one load may deviate with changes of load and temperature and possibly with time. If the diodes are not also matched on inverse characteristics, current distribution will also vary, to some extent, with variations of applied voltage.

3. *Ballast resistors.* Effective only when the resistance drop is made a significant part of the total drop. Losses are increased in proportion. When used with coded diodes the resistance drop of protective fuses may assure sufficient balancing.

4. *Derating factors.* In any of the preceding three methods, derating factors are generally applied as some function of the number of diodes in parallel, for purposes of reducing the percentage of failures caused by overloaded cells. Discussed in more detail subsequently.

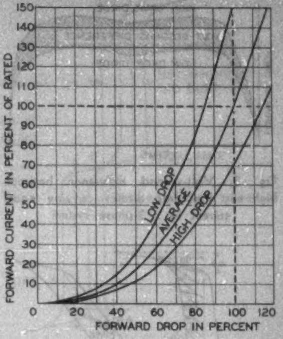

Fig. 2. Peak forward current plotted against peak forward voltage drop for a particular type of diode, based on the average

5. *Current-balancing reactors.* Discussed in detail subsequently.

Resistors, in varying degree, reduce the potentially high efficiency of semiconductor rectifiers. In low-voltage applications, where the total power is small despite high currents, this may not be very serious. Improved current balance by means of matched diodes is burdensome, and will remain so until improved manufacturing techniques provide better control of the forward drop than at present. The use of drastic derating factors is an expensive necessity in the absence of other means of current balancing. For holding down the percentage of cell failures, factors have been proposed which reduce the rating of each additional cell, in arithmetical or geometrical progression: In some cases the point of diminishing returns is approached very rapidly, and a further addition of cells does not increase sufficiently the total rating of the rectifier to justify them.

In view of these circumstances the use of balancing reactors deserves careful consideration, not only from the standpoint to technical correctness, but as a matter of economic advantage. In this respect we must not overlook the importance of continuity of service and cost of maintenance.

THEORY OF OPERATION

The current-voltage characteristics of similar commercial diodes fall on either side of the average characteristic, and are roughly parallel to each other. Therefore, the difference in voltage drop between two diodes, paralleled through balancing means so as to carry equal currents, will be substantially constant

and in the same sense during most of the conduction period. Fig. 3 illustrates this mode of operation, and the shaded area represents the volt-seconds that must be absorbed by the balancing reactor. This area translated into flux linkages fixes the minimum cross section of iron and the number of turns of the reactor. The unbalance between the two diodes at any instant is the instantaneous magnetizing current required to produce the flux change represented by the volt-second area up to that time.

The degree of balance therefore depends on the quality of iron and of structure used in the reactor. It is to be expected that, in the simplest form of reactor, without any means of flux reversal or resetting, the core will be excited beyond, and return to, its residual flux density at the end of each conduction period. Even if the voltage difference between the two diodes is very small, the volt-seconds created in successive cycles are cumulative, and starting at zero, will soon reach the residual flux density. This is illustrated in Fig. 4(A) which is based on a typical, oriented transformer iron core without air gap. Fig. 4(B) illustrates the behavior of a similar core built with a small air gap. The magnetizing current is increased over the full range of flux density, but the residual flux is so much lower that the average current over the useful range is less than in the reactor without any air gap. Unfortunately, the requirements of low magnetizing current and low residual flux work in opposite directions.

For a reasonably close approximation an average can be taken of the magnetizing current over the conduction period, for the range of flux densities over which the reactor will be working, and this average can be applied to the peak diode currents for a determination of the amount of unbalance. Since the magnetizing current can affect the diode current only during the conduction period, the unbalance expressed in average current over the full cycle is only one-third of the magnetizing current when operating in a 3-phase system. The unbalance of the diode rms currents is the magnetizing current divided by $\sqrt{3}$.

Reactor Systems

The simplest system of balancing reactors is obtained when only two diodes are to be paralleled, in which case a single, center-tapped reactor fulfills the requirements. When four diodes are to be paralleled, a whiffletree arrangement, as illustrated in Fig. 5, can be employed. This is still a fairly simple arrangement, but one of the three reactors carries the total current of the other two, and must therefore be of a different design. The maximum unbalance current between the highest and lowest diode can be as great as the magnetizing current of one of the smaller reactors or of half of the larger one.

The whiffletree arrangement can be extended to balance 8, 16, 32, or 2^n diodes. If the number is other than a power of two, unsymmetrical variations of the whiffletree can be devised to accommodate them. Any number of diodes can be handled by multiwinding reactors, but in general such reactors are uneconomical and connections to them complicated.

The small voltage differences between similar diodes, and the size of conductors required in power equipments, make the through type of construction very attractive from the standpoint of losses, space, and economy. In this type there are only two conductors in the core window; they carry the currents of two diodes in opposite directions. The difference between these currents is the net magnetizing current acting on the core.

With such reactors, it is relatively simple to balance each diode against its immediate neighbor in "chain" fashion, as shown in Fig. 6. The greatest unbalance will occur if all the diodes in one-half of the chain are in the highest voltage-drop class, and all those in the other half in the lowest voltage-drop class. Since adjacent conductors thread the same core in opposite directions, the greatest instantaneous unbalance between them cannot exceed the instantaneous magnetizing current of that core, i_m. Each diode will, therefore, carry a current equal to the average current of all the diodes, plus or minus some factor of magnetizing current, as indicated in Fig. 6 for 10 diodes. In the case of "n"

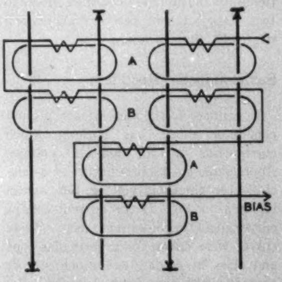

Fig. 8. Two-way biased reactors

VoL.
Pt. 1
195

diodes in an open chain, the maximum deviation from the average, taken over a full cycle, is $\Delta I_{av}=(1/6)(n-1)i_m$ in a 3-phase system.

If the chain is closed on itself by adding one more core ahead of the first diode and threading through that core the lead of the last diode, balancing voltages are transmitted in two directions at the same time. This produces the current distribution shown in the second line of Fig. 6. The maximum unbalance is reduced by approximately one-half, and $\Delta I_{av}=(1/12)ni_m$.

This method can be used when not too many diodes are connected in parallel. When large numbers of diodes are paralleled, the closing lead, shown as a dotted line in Fig. 6, becomes undesirably long. A better way which eliminates this long lead and offers other structural advantages, is to double the chain back on itself, as shown in Fig. 7. All diode leads are short and conveniently arranged.

Design of Reactors

As previously mentioned, oriented, magnetic-steel cores, either rolled or punched, without air gaps, would have the smallest magnetizing current and highest maximum flux densities, and also, unfortunately, the highest residual flux densities. When using only air gaps or lower quality steels to reduce the residual flux, one must make a careful comprise to obtain the best balance with the least material and space.

There are many ways of reducing the residual flux electrically, but the greater complexity of the system needed for this may not be justified. For instance, each reactor may be made up of two cores, each core oppositely biased, as in Fig. 8. The magnetic diagram for this system is given in Fig. 9; it is obvious that the system comes to rest at point *O* at the end of each conducting period. The bias ampere-turns must be slightly greater than the magnetizing current of each core component, and the net magnetizing or unbalance current will therefore be slightly greater than twice the magnetizing current of the core without bias. Nevertheless, since the core can be made of the best magnetic material, without an air gap, the unbalance current will still be very small. It should be noted, however, that one core will be idle most of the time, yet must be furnished unless the direction of unbalance can be predicted and maintained. It becomes a matter of economy to decide whether two small cores with bias windings are more desirable than a single core containing more iron but having no windings or bias supply. The same reasoning must be applied to other electrical means of reducing the residual flux of single cores, but these again involve secondary windings and a certain amount of auxiliary apparatus.

Up to the present time it appears that even though reactors without flux-resetting means make poor use of the iron, the relative cheapness of the material and labor involved make the simple through-type reactor the most economical. Preformed, wound cores with one or more air gaps are commercially available and offer a good solution to the problem. Another very satisfactory and economical solution is a stack of punched laminations, as illustrated in Fig. 10(A). Cold-rolled transformer steel, oriented lengthwise, without air gap, has proved surprisingly satisfactory. The cross orientation around the ends of the slots reduces the residual flux to a tolerable level. It has been found expedient, however, to slit some of the laminations lengthwise, as shown in Fig. 10(B), so as to provide a partial air gap.

Test Results

The strip-type structure of Fig. 10(A), without closure, was tested with 12 150-ampere 94-PIV (peak inverse volts) germanium cells, loaded in a half-wave circuit to 1,570 amperes d-c total. The cells were not matched, and were placed at random. The results of this test are shown in Fig. 11. Curve *A* shows the current distribution among diodes without any balancing iron; the maximum deviation amounts to 65% from the average diode current. Curve *B* shows the current distribution with balancing iron having no air gap; the maximum deviation is 7.5% from average. Curve *C* gives the distribution with a percentage of the laminations slit longitudinally, as in Fig. 10(B), to provide a partial air gap; the maximum deviation was reduced to 4.0%.

Conclusion

Especially when it is desired to connect both ends of the diodes to paralleling busses so as to take advantage of liquid-cooled busses, and of the voltage divider system described in an earlier paper, it becomes important to develop a simple balancing reactor which will not greatly increase the space requirements, the complexity, and the cost of a large rectifier. Fig. 12 shows the compact and convenient layout of one phase of a 5,000-ampere section of a 10,000-ampere 300-volt silicon rectifier using two series-connected banks of 20 parallel

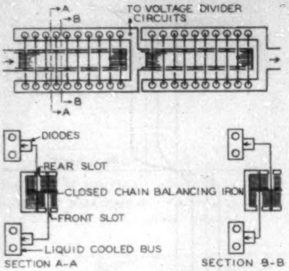

Fig. 12. Compact arrangement for 20 diodes in parallel, 2 sets in series

diodes each. The balancing iron is of the form shown in Fig. 13. The busses are liquid-cooled, and the diodes mounted on them can be replaced without breaking into the cooling system. Voltage distribution across the series cells is rigidly fixed by the method described in reference 1.

The closed-chain arrangement of reactors lends itself readily to rectifiers of this class. It is worth keeping in mind, too, that the maximum predicted unbalance will seldom occur unless magnetizing currents are excessive; i.e., it is unlikely that half the diodes will have the highest voltage drop, and half the lowest voltage drop, of a class, and that they will be nicely segregated at opposite ends of the chain.

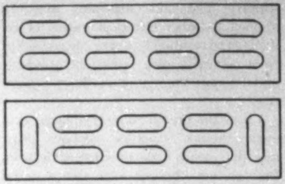

Fig. 13. Punched-strip closed-chain reactor

There has been much work in various places and along various lines to overcome the disadvantages of dissimilar diode characteristics. The application of drastic derating factors to compensate for the poor distribution of voltage and current even among coded diodes must be considered based on a wasteful philosophy of necessity, and is not justified. In small rectifier units using few cells, current and voltage balancing are both easy and inexpensive to accomplish. In large units the need and advantages are obvious:

1. Operation of each diode under the conditions for which it was intended is assured.
2. The cost is offset by the saving in cells which are otherwise required by derating.
3. The added space is offset by the space requirement of extra cells.
4. The operation of diodes at rated current and voltage should assure longer life, and result in savings for the user, the equipment manufacturer, and the diode manufacturer.
5. Operation of diodes within their ratings should improve reliability and availability of the equipment, and reduce maintenance problems.
6. The complete elimination of coding, or at least the broadening of classifications, is important to the user in the reduction of stock items, the chances or error, and in availability. It is hardly less important to the manufacturer.

As the technology of semiconductor diodes improves, and larger ratings with closer tolerances become available, the need for balancing may be reduced. It seems likely, however, that unit ratings will also go up, still requiring banks of cells in parallel, and possibly in series. The greater cost and percentage of unit rating invested in each large cell will probably justify balancing arrangements, even though manufacturing tolerances are greatly improved.

Discussion

A. A. Halacsy Federal Pacific Electric Company, Newark, N. J.): I would like to ask, referring to Figs. 12 and 13 of this paper, what insulation is used on the steel laminations, and especially what is the thickness of this insulation? Second, are the two kinds of laminations interleaved, or is one kind used for half of the stack and the other kind used for the other half of the stack? Third, was any magnetic leakage observed from one kind of lamination to the other kind of lamination, which would result in a closed magnetic path around one conductor only, or was this leakage so small that it could not be observed at all?

I. K. Dortort: Mill-coated transformer steel was used in the strip reactors of Figs. 10, 12, and 13. No insulation was added between laminations.

The two kinds of laminations are purposely arranged in two separate stacks, one above the other as shown in Fig. 10, and separated by a strip of insulating material. Any appreciable interchange of flux between the two stacks must take place across the insulating spacer as well as the gaps between laminations close to the separator.

The maximum magnetomotive force in the iron around the complete loop is very small even at maximum flux density. Even if all the available ampere-turns were to appear across the effective air gap, the flux density in the air gap would be negligibly small. For this reason no attempt was made to observe or measure this "leakage flux."

Magnetic-Amplifier-Operated Ink Recorders

W. A. GEYGER
MEMBER AIEE

Synopsis: The purpose of this paper is twofold. It is intended to describe in a summarizing way the specific properties of magnetic amplifiers with regard to instrumentation. It is also particularly concerned with the application of self-balancing magnetic-amplifier techniques in the realm of moving-coil ink recorders and ink oscillographs.

The paper, therefore, presents detailed information on design and actual performance of high-precision magnetic instrument amplifiers exhibiting unusual stability of operation, linearity of the output-input characteristic, and freedom from zero drift. Such d-c amplifiers offer the general advantages of elimination of movable parts and vacuum-tube components, sturdiness and reliability, and almost unlimited life. They are, therefore, very practical for long-time reliability testing of various circuit components such as high-sensitivity relays, where absolute reliability of the d-c amplifier, which operates the ink recorder, is of prime importance. Actually, amplifier-input signal voltages of the order of 10 to 100 mv (millivolts) and amplifier-input signal currents of the order of 2 to 50 μa (microamperes) have been used successfully for operating standard-type moving-coil ink recorders and ink oscillographs without impairing the accuracy of measurements.

Magnetic-amplifier-operated ink recorders are also well suited to perform mixing of signals; i.e., algebraic summation of signal voltages and signal currents. Multiplication of signals may be performed by means of two thermocouples, one of which is heated by the algebraic sum of two derived currents, and the other by their difference. Another possibility to perform multiplication consists in replacing the two thermocouples by two magnetic-amplifier multiplying circuits, which act as square-low means and provide the square term of the algebraic sum of two derived currents, and the square term of their difference, respectively.

A Brush-type ink oscillograph in conjunction with a 400-cycle-operated 2-stage or 3-stage magnetic amplifier has been used for recording 30-cycle signals with attenuation not exceeding 5%. The paper presents samples of typical ink oscillograms which have been obtained by recording variable-frequency sinusoidal-waveshape and square-wave signals. Through the use of a very large amount of negative feedback in self-balancing magnetic amplifiers, extreme stability with regard to zero drift and constant gain is assured in various ink-recorder applications.

THE HISTORICAL development of the magnetic-amplifier art[1,2] makes it evident that there is a very close linkage between saturable-reactor devices and electrical measurements. Pertaining patents, scientific papers, and technical reports may be divided into main groups. The first group deals with various methods for performing measurements on magnetic amplifiers and similar devices, to obtain information concerning basic principles of operation, steady-state characteristics, and dynamic performance of such amplifiers. The second group is concerned with the application of magnetic amplifiers in instrumentation; e.g., measurement of large direct currents and high direct voltages, extending the sensitivity of electric instruments, and operation of high-speed self-balancing potentiometers and bridge networks with magnetic servo-amplifiers.

In order to replace the very sensitive and delicate instruments, as used in connection with various forms of transducers (thermocouples, photoelectric cells, resistance-thermometer circuits, resistance strain gages, etc.) by rugged indicating and recording instruments, a d-c amplifier with adequate zero stability and stable, linear characteristic must be interposed between the transducer and the instruments. Such d-c amplifiers are particularly suitable for extending the sensitivity of electrical multirange instruments and moving-coil ink recorders. They may also be used in connection with phase-sensitive rectifiers for the measurement of various a-c quantities, for example, in a-c potentiometer circuits and a-c bridge networks. Voltage dividers and shunts may be provided to extend the voltage and current ranges of such arrangements.

In instrument applications, the magnetic amplifier is used either as an "all-magnetic" device or as a magnetic modulator in combination with vacuum tubes or transistors. In the first case, single-stage or multistage magnetic-amplifier push-pull circuits utilizing over-all negative feedback for stabilization have been successfully used in various forms. Although speed of response is generally of minor importance in these applications, the basic requirements of adequate zero stability and stable, linear output-input characteristic (accuracy about 1 to 2% of full-scale indication of the instrument) are sometimes difficult to satisfy. In the second case, either a fundamental-frequency-type or a second-harmonic-type magnetic amplifier (or flux-gate magnetometer[3]) is combined with a conventional a-c vacuum-tube amplifier and a phase-sensitive rectifier; and over-all negative feedback is utilized for stabilization. Such arrangements represent carrier-frequency types of d-c amplifiers using a magnetic modulator for converting the d-c signal of the transducer into an a-c signal applied to the input of the vacuum-tube amplifier.

Self-balancing magnetic amplifiers[4–6] employing combination of magnetic positive feedback and electric (galvanic) negative feedback exhibit unusual stability, linearity, and freedom from zero drift, which are requirements of prime importance in electric-instrument applications. These amplifiers offer the possibility of reducing actual response time to its minimum value of one-half cycle of the power-supply frequency. For instance, when using a power-supply frequency of 400 cps (cycles per second), the amplifier reaches 100% of its final steady-state output current 1.25 msec (milliseconds) after the transient signal voltage is applied; and the output current drops to zero 1.25 msec after the signal voltage is suddenly removed.

This paper is concerned with the application of self-balancing magnetic amplifier technique in the realm of moving-coil ink recorders and ink oscillographs. Such high-precision "magnetic instrument amplifiers" are very practical for long-time reliability testing of various circuit components; e.g., high-sensitivity relays, where absolute reliability of the d-c amplifier, which operates the ink recorder, is of prime importance. There have been even some cases, where the operation of the components to be tested has proved to be more reliable than that of the amplifier of the recorder. In such situations, the investigator may then ask whether the reliability of the components to be tested

Paper 58-541, recommended by the AIEE Recording and Controlling Instrumentation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Middle Eastern District Meeting, Washington, D. C., April 28–30, 1958. Manuscript submitted January 20, 1958; made available for printing February 21, 1958.

W. A. GEYGER is with the U. S. Naval Ordnance Laboratory, Silver Spring, Md.

The author wishes to express his appreciation to B. T. Hooper, A. D. Krall, and W. Raskin for their helpful co-operation in conducting the oscillographic investigations. Indebtedness is also acknowledged to W. P. Christoph for valuable discussions regarding multiplying circuits and various applications of magnetic-amplifier-operated ink recorders.

or that of the amplifier, which drives the moving-coil ink recorder or ink oscillograph is being tested.

Recently, a considerable part of the author's activity has been concentrated on special forms of magnetic amplifiers for standard-type moving-coil ink recorders and ink oscillographs. This work has been directed toward the operation of Esterline-Angus and Brush recorders with self-balancing magnetic amplifiers working under either voltage-balance or current-balance conditions. With regard to various special instrumentation problems, these d-c amplifiers have proved to be powerful tools for providing extremely stable magnetic-amplifier-operated ink recorders. Such recorders are also well suited to perform algebraic summation and multiplication of signal voltages or signal currents by means of thermocouples or magnetic-amplifier multiplying circuits acting as square-low means, respectively.

An important part of these investigations has been concerned with the combination of a Brush recorder with a 400-cycle-operated multistage magnetic instrument amplifier, each stage of which has a response time of one-half cycle of the power-supply frequency (1.25 msec). Variable-frequency sinusoidal-waveshape and square-wave signals have been employed for testing the dynamic performance of these arrangements. Typical ink oscillograms proved that it is possible to perform in this way recording of 30-cycle signals with attenuation not exceeding 5%.

When employing a conventional 1-ma (milliampere) 1,500-ohm Esterline-Angus recorder, amplifier-input signal voltages of the order of 10 to 100 mv and amplifier-input signal currents of the order of 2 to 50 μa have been used for operation of the recorder without impairing accuracy of measurements. In this case, the response time of the 60-cycle-operated magnetic instrument amplifier is of the order of 100 msec, or even more. Through the use of a very large amount of negative feedback in this amplifier, extreme stability with regard to zero drift and constant gain is assured in various ink-recorder applications.

Basic Considerations on Magnetic Instrument Amplifiers

General

The relationship between power gain, response time, and stability of a magnetic amplifier is such that if one property is accentuated, it is always at the expense of the the other properties. Recognition of this fact is particularly important with regard to magnetic amplifiers to be used in instrumentation.

For example, in conventional external-feedback or self-saturating magnetic-amplifier circuits, the dynamic power gain D_P, i.e., the ratio of usable power gain K_P over control time constant T_C (sometimes called the "figure of merit"[7]), is given by the equation

$$D_P = \frac{K_P}{T_C} = 4f_P \frac{R_L}{R_O} K_{AT} k_f^2 \tag{1}$$

or

$$D_P = 4\frac{R_L}{R_O} K_{AT} k_f^2 \text{ per cycle} \tag{2}$$

where f_P is the power-supply frequency, R_L is the load resistance, R_O is the total resistance of the load circuit, K_{AT} is the ampere-turn gain, and k_f is the form factor; i.e., the ratio between rms value and average value of the current in the load circuit. On the other hand, in these conventional circuits, the drift is proportionally linear to the actual value of ampere-turn gain K_{AT}. Obviously, the drift can be reduced by reducing K_{AT}. However, because the ratio of gain reduction over drift reduction is constant, the gain will be reduced at the same rate.[8]

In self-balancing magnetic amplifiers, a very significant reduction of drift is obtained by reducing the effective (total) feedback factor,[9] which is a measure for the stability of operation. This has been achieved by combination of the dynamic gain-increasing effect of magnetic positive feedback and the drift-reducing effect of electric negative feedback, resistance-coupled into the control-circuit loop.

The Evolution of the Self-Balancing Magnetic Amplifier

The ordinary saturable reactor is characterized by the fact that, over certain ranges, the average value of load current is substantially independent of large variations in magnitude, frequency, and waveshape of the power-supply voltage, and considerable changes in load resistance. Therefore, it is possible to employ ordinary saturable reactors with high-permeability rectangular-hysteresis-loop core material as d-c instrument transformers for measurement of large direct currents and high direct voltages. This function is based upon the current-transformer character ("law of equal ampere-turns"[10]) which is the result of inherent negative-feedback properties ("intrinsic" negative feedback) of the ordinary saturable reactor having either series- or parallel-connected a-c load windings. Moderate power amplifications can be obtained with such simple arrangements when the load resistance R_L is properly matched to the impedance values of the saturable-reactor output circuit so that the output power P_L is greater than the input power P_C, representing the actual losses in the d-c control circuit. The value of the power gain $K_P = P_L/P_C$ (about 10 to 100) depends on the design and size of the saturable-reactor elements preferably having spirally wound tape cores with multilayer toroidal windings.

In order to obtain much higher values of amplification ($K_P = 1{,}000$ to 10,000, or more), it is common practice to apply a very large amount of positive "extrinsic" feedback by means of external-feedback or self-saturating circuits for reducing or nearly nullifying the intrinsic negative feedback of the ordinary saturable reactor. By connecting a high resistance (sometimes termed "forcing resistor") in series with the d-c control windings, it is possible to obtain well-known static and dynamic performance characteristics of such extrinsic-feedback types of magnetic amplifiers, as expressed, e.g., by ampere-turn gain, power gain, control time constant, and dynamic power gain (figure of merit).

Although conventional forms of external-feedback or self-saturating magnetic-amplifier circuits have proved very suitable for many applications, these circuits generally do not meet the severe requirements where very high power gain (high sensitivity), extreme stability with regard to zero drift and constant gain, and high speed of response are of paramount importance. When applying quantity-production techniques, these performance characteristics of the magnetic amplifier must be secured with a minimum of core-matching and component selection.

The aim of the research and development work on magnetic amplifiers of the self-balancing potentiometer type[4] consisted in combining the inherent extremely stable operating conditions of the ordinary saturable reactor, as used in d-c instrument transformers[11,12] with the unique features of high-precision self-balancing potentiometer devices and negative-feedback amplifiers. In these self-balancing magnetic amplifiers, extrinsic magnetic positive feedback (external feedback or self-saturation) is provided for completely nullifying the intrinsic negative feedback of the ordinary saturable reactor (infinite internal gain or "critical regeneration"[4–6]). Additionally, extrinsic electric negative feedback (resistance-coupled into the control-circuit loop) is applied to obtain very stable operating conditions of the amplifier, similar to those of d-c instrument transformers. In this way, by combining the dynamic gain-increasing effect of magnetic positive feedback with the drift-reducing effect of electric negative feedback, a very significant reduction of drift is obtained, because the effective feedback factor of the self-balancing magnetic amplifier is considerably reduced.[6] Operating under "voltage-balance" or "current-balance" conditions of the control circuit, this amplifier demands practically no energy from the d-c signal source; e.g., a thermocouple or a phase-sensitive rectifier circuit. Because the average value of the control-winding current is substantially zero for the entire working range of the amplifier, the output-input characteristic is linear (the linearity error is of the order of 0.1% or less). Over certain ranges, large variations in magnitude, frequency, and waveshape of power-supply voltage, load resistance, and control-circuit resistance have no appreciable effect upon the transconductance, voltage ratio, current ratio, or transresistance of the amplifier. The very large amount of electric negative feedback used makes the gain of the amplifier essentially independent of all factors except the accuracy of the resistors in the negative-feedback network.

Self-balancing magnetic amplifiers operate under extremely stable conditions with a large over-all power gain (about 1,000 to 10,000 in a single-stage design) and a high speed of response (the response time may be reduced to its minimum value of one-half cycle of the power-supply frequency). On the other hand, for special applications, the transient-response characteristics may be altered materially through the use of integrating circuit elements in the degeneration network of the amplifier. Of course, in this case too, the relationship between power gain, response time, and stability of operation is such that if one property is accentuated, it is always at the expense of the other properties. Results of various experimental investigations have shown that the actual behavior of self-balancing magnetic amplifiers approximates very closely corresponding characteristics of an ordinary saturable reactor with stabilizing negative-feedback properties (intrinsic negative feedback).

Operation of Magnetic Amplifiers with Magnetic Voltage Stabilizers

ELEMENTARY IDEAS

The significant fact that the output-input characteristic of an ordinary saturable reactor and that of a properly designed self-balancing magnetic amplifier is substantially independent of large changes in voltage E_P and frequency f_P of the a-c power supply means that actual value of magnetic-flux density in the cores, $B = \text{constant} \times E_P/f_P$, may change within wide limits without appreciably affecting the performance of such arrangements. However, when the problem consists in providing very small input-voltage ranges; e.g., 0–5 mv or 0 to ±2.5 mv, then flux-density variations, as caused by voltage fluctuations of ±10% and frequency variations of ±5%, may produce excessively large zero-drift errors and changes of the output-input characteristic. In such cases, application of additional means for eliminating undesirable changes of actual value of flux density in the magnetic-amplifier cores has proved to be necessary. In 1940, the author showed[13] that the magnetic voltage stabilizer,[14] a cousin of the magnetic amplifier, is extremely suitable for this purpose. Magnetic voltage stabilizers consisting of transformer-like structures and capacitors (ferroresonant circuits) have no moving parts of vacuum tubes and can perform and added function of a step-up or step-down transformer, eliminating the use of additional transformer components.[15] When employing such ferroresonant saturating-reactor circuits, as used in some types of frequency meters,[16] the average value of output voltage; i.e., the supply voltage of the magnetic amplifier, is linearily proportional to power-supply frequency: $E_P = \text{constant} \times f_P$. Thus, the flux density $B = \text{constant} \times E_P/f_P$ in the magnetic-amplifier cores will be substantially independent of voltage fluctuations of ±10 to 20%, and frequency variations of ±5 to 10%. In this way, by replacing the ordinary power-supply transformer of the magnetic amplifier by a small nickel-iron-alloy constant voltage transformer,[17] it is possible to eliminate the undesirable effects of voltage drift and frequency drift, and to obtain improved performance of low-level magnetic amplifiers.

Operation of self-balancing magnetic amplifiers with magnetic voltage stabilizers makes it possible to combine the specific advantages of both artifices and to obtain optimum performance. This is, of course, particularly significant for low-level d-c signal applications and for solutions of those special problems where extremely small values of linearity error and zero drift represent prime requirements.

MEASUREMENTS ON HALF-CYCLE-RESPONSE MAGNETIC AMPLIFIERS

The transient response of magnetic amplifiers with rectangular-hysteresis-loop core material can be described by simple linear equations.[18] When operating in the linear region of the output-input characteristic, the response of the load current to changes of d-c control voltage, power-supply voltage, and load resistance is an exponential function, governed by a "time constant," which varies with the load resistance and inversely with control-circuit resistance and power-supply frequency. It follows from equation 1 that the "control time constant" T_C can be expressed as follows:

$$T_C = \frac{1}{4f_P} K_P \frac{R_O}{R_L} \frac{1}{K_{AT}} \frac{1}{k_f^2} \text{ seconds} \qquad (3)$$

or

$$T_C = \frac{1}{4} K_P \frac{R_O}{R_L} \frac{1}{K_{AT}} \frac{1}{k_f^2} \text{ cycles} \qquad (4)$$

It is also possible to express the control time constant T_C by introducing the overall volts-per-turn gain. For example, the time-constant relationship of a self-saturating magnetic-amplifier circuit is

$$T_C = \frac{1}{2f_P} \frac{d(E_T/N_A)}{d(E_S/N_C)} \text{ seconds} \qquad (5)$$

or

$$T_C = \frac{1}{2} \frac{d(E_T/N_A)}{d(E_S/N_C)} \text{ cycles} \qquad (6)$$

where $E_T = E_L R_O/R_L$ is the average value of the total output voltage, N_A is the number of turns of the output (gate) windings, E_S is the average value of the input (control) voltage, and N_C is the number of turns of the input (control) windings.

In considering the accuracy of this theoretical method for determining the speed of response of conventional types of magnetic amplifiers having a response time of about 6 to 30 cycles, or more, it must be remembered that in most practical design problems an approximate value is all that is required. However, in regard to the transient performance of high-speed magnetic amplifiers having a response time of the order of 1 to 4 half-cycles of the power-supply frequency, experimental methods have assumed increasing importance in their development.

Convenient and accurate methods for analyzing the dynamic performance of slow-response magnetic amplifiers consist in applying half-cyclic integrators which supply information about the half-cyclic average of the output throughout a transient[19] or in the steady-state with periodic signals.[20] The dynamic performance of fast-response magnetic amplifiers may be analyzed by means of a transient analyzer[21,22] which produces a synchronous square-wave signal voltage and permits

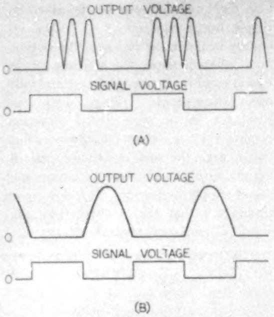

Fig. 1. Schematic waveshape diagrams characterizing half-cycle transient response of self-balancing magnetic amplifiers

A—The amplifier is 1,200-cycle-operated from a 400/1,200-cycle magnetic-frequency tripler, whereas the synchronous 400-cycle square-wave signal voltage is derived from a ferroresonant circuit

B—The amplifier is 400-cycle-operated directly from the power supply, and the synchronous 400-cycle square-wave signal voltage is derived from a ferroresonant circuit, which is also fed from this power supply

direct visual observation of a stationary pattern on a dual-beam oscilloscope. Application of the simple magnetic-amplifier transient analyzer employing a synchronously operated mechanical-switch device[21] is limited to low power-supply frequencies (e.g., 50 to 60 cps), where a mechanical switch can be operated in a reliable way. When working with higher power-supply frequencies (e.g., 400 to 2,000 cps), the synchronously operated switch device representing a mechanical modulator may be replaced by any suitable type of electric modulator; e.g., a magnetic switch[22] which consists essentially of a special saturable-reactor circuit producing an auxiliary current with rectangular waveshape. In this case, the magnetic amplifier under test may be supplied from a magnetic frequency multiplier[23] which produces an exact multiple of the frequency of the a-c power supply feeding directly the saturable-reactor circuit acting as a magnetic switch.

Fig. 1(A) shows schematically a typical waveshape diagram characterizing the half-cycle transient response of a single-stage self-balancing magnetic amplifier, as described previously.[24] The lower trace indicates the waveshape of the synchronous 400-cycle unidirectional square-wave signal voltage derived from the phase-shifter voltage of a magnetic-switch circuit. The upper trace shows the half-cycle transient response of the output voltage of this amplifier which is 1,200-cycle-operated from a 400/1,200-cycle magnetic frequency tripler.

A simplified and very convenient method for studying the transient performance of half-cycle response magnetic amplifiers consists of eliminating the frequency tripler, and feeding both the amplifier under test and the phase shifter of the magnetic-switch circuit directly from the a-c power supply; e.g., both with 60 or 400 cps. Fig. 1(B) shows schematically the respective waveshape diagram corresponding to the special case that the phase relationship between square-wave signal voltage (lower trace) and half-cycle pulses of the magnetic-amplifier output voltage (upper trace) is exactly 180 degrees.

Fig. 2 illustrates the simplified test circuit for measurements on half-cycle response magnetic amplifiers. The 60-cycle or 400-cycle 3-phase power supply feeds both the magnetic-amplifier circuit under test, as described in later sections of this paper, and a phase shifter which operates a ferroresonant magnetic-switch circuit (magnetic voltage stabilizer) consisting of a nonlinear reactor T_P with almost rectangular magnetic characteristic (saturating reactor with Orthonol tape core), a capacitor C_P, and a linear reactor L_P. In this special case, the square-wave voltage E_{SQ} (60 cps or 400 cps, respectively) is applied to a splitting circuit carrying the square-wave alternating current I_M (without d-c component). This splitting circuit consists of two half-wave rectifiers (silicon junction diodes) D_M', D_M'', with potentiometer resistor R_M' ("black" first-half-cycle pulses I_M') and fixed resistor R_M'' ("white" second-half-cycle pulses I_M''). The load voltage E_L and the variable square-wave signal voltage E_S are applied to the channels V_1 and V_2 of the dual-beam oscilloscope. When using this test circuit, the dual-beam oscilloscope displays input and output voltages of the magnetic amplifier under test simultaneously and continuously on common time base. Thus, it is possible to study the effect of various circuit-parameter changes on actual dynamic performance and to determine optimum design.

Self-Balancing Push-Pull Magnetic-Amplifier Circuits for Operation of Ink Recorders

General

In magnetic-amplifier-operated ink recorders, push-pull action is used to obtain output polarity that depends on the signal polarity (duodirectional output-input characteristic). Two equally rated saturable-reactor systems (the "plus-minus system" and the "minus-plus system") are back-to-back connected in such a way that either the voltages produced by them across the load, or the currents drawn by them through the load, are in opposition. Other significant advantages of push-pull types of magnetic-amplifier circuits reside in the facts that the output-input characteristic passes through the origin, that linearity and stability are considerably improved, and that multi-stage design (cascading of two or three stages) is greatly facilitated. These additional advantages are so important that push-pull arrangements are sometimes employed in those cases where duodirectional output-input characteristic is not required; i.e., when the signal voltage or signal current does not change its polarity.

Generally, four saturable-reactor elements are incorporated in a symmetrical a-c bridge or differential-type circuit operating on a-c bridge balance conditions: Output is zero if input is zero. In practice, it is required that fulfillment of this condition (the zero stability) must be mostly independent of changes in magnitude, frequency, and waveshape of the

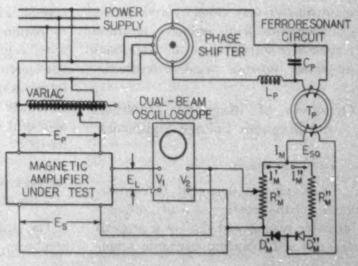

Fig. 2. Simplified test circuit for measurements on half-cycle-response magnetic amplifiers using the new method, as characterized by the schematic waveshape diagram of Fig. 1(B)

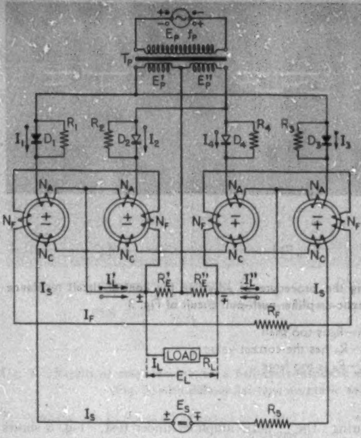

Fig. 3. The basic self-saturating push-pull circuit with differential-type magnetic negative feedback

power-supply voltage, major changes in ambient temperature, etc. In other words, the zero drift of the magnetic-amplifier circuit with regard to such changes in operating conditions shall be as small as possible. According to conventional practice in defining the performance of electric instruments, it is advisable to distinguish between drift-rate components, such as voltage drift, frequency drift, temperature drift, etc.

Feedback in Magnetic-Amplifier Push-Pull Circuits

In the orginal forms of magnetic-amplifier push-pull circuits with two single-ended external-feedback or internal-feedback (self-saturating) circuits in back-to-back connection,[25] each of these circuits has its own positive-feedback component which reduces or nearly nullifies the intrinsic negative feedback of the ordinary saturable reactor (transductor). These individual feedback components, however, are unaffected by the output-circuit design.

In contrast to these original forms of push-pull arrangements, magnetic amplifiers of the differential-feedback type[26,27] utilize feedback derived from the load circuit, which is common to both saturable-reactor systems. The resultant differential feedback, which may be positive or negative as required, is proportional to the actual difference between the individual load currents and is zero with no-signal conditions. As a result, the magnitude of individual quiescent currents (load currents with no-signal conditions) is unaffected by differential feedback, which may be derived from either output voltage (differential voltage feedback) or output current (differential current feedback).

Differential feedback may be produced by additional windings, which are inductively coupled with the control windings (magnetic feedback[26,27]). In this case, the differential-feedback circuit does not have any influence upon the effective input resistance of the control circuit; and the effective control-circuit impedance is determined solely by the actual total resistance of this circuit, comprising the resistance of the control windings and a series resistor (forcing resistor) which is conventionally provided to increase the speed of response of the magnetic amplifier. These arrangements are sometimes termed "self-excited" or "pseudo-feedback" circuits, because they do not have the inherent property of influencing the actual magnitude of the input-circuit resistance, as for example, the electronic amplifier of the cathode-follower type does.

In 1944, the author[28,29] showed that "true feedback" ("electric" feedback) can be applied to magnetic amplifiers, particularly for instrumentation purposes, by feeding back a voltage or current, proportional to the actual load current, resistance-coupled into the control-circuit loop so that a very large amount of degeneration is obtained. In this arrangement, a push-pull-type magnetic amplifier acting as a d-c/a-c converter or modulator is employed in conjunction with an ordinary a-c vacuum-tube amplifier and a phase-sensitive rectifier; and over-all negative differential feedback is utilized for stabilization of the system. Combination of this arrangement with a moving-coil ink recorder offers the possibility of making a permanent record of very small direct voltages or current created, for instance, by thermocouples, photoelectric cells, or radiation pyrometers.

This paper, however, is concerned only with all-magnetic devices employing no vacuum-tube or transistor components, and having inherent self-balancing potentiometer characteristics. Experience has shown that such magnetic-amplifier-operated ink recorders are preferred in many situations, particularly for long-time reliability testing of circuit components, where absolute reliability of the d-c amplifier, which operates the ink recorder, is of prime importance.

There are various types of magnetic-amplifier push-pull circuits utilizing either external feedback[30] or internal feedback (self-saturation[31]), which may be employed in conjunction with ink recorders. Self-balancing magnetic amplifiers of the differential-feedback type with bias excitation and external-feedback circuits have been described in detail previously.[32,33] These amplifiers contain a comparatively large number of rectifier elements (12 half-wave rectifiers in each stage). The simplified push-pull circuits described in the following sections, however, employ self-saturation and contain

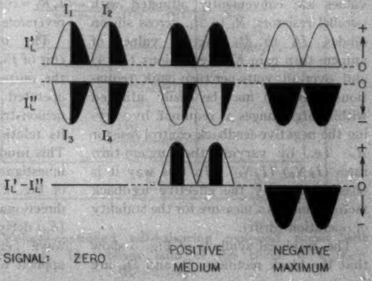

Fig. 4. Variations of the average values of the half-cycle pulses I_1 to I_4, and waveforms of the resultant full-wave unidirectional currents I_L', I_L'', and $I_L' - I_L''$ for the special case that, with no-signal conditions, the firing angle of the four saturable-reactor elements (Fig. 3) is 90 degrees

only four half-wave rectifier elements (preferably silicon junction diodes) in each stage. They have been used successfully in 2-stage and 3-stage designs. In these multistage arrangements, the input-stage circuit with Supermalloy tape cores and silicon rectifiers is supplied from a ferroresonant constant-voltage transformer to improve stability of operation with regard to zero drift and constant gain.

THE BASIC SELF-SATURATING PUSH-PULL CIRCUIT WITH DIFFERENTIAL-TYPE MAGNETIC NEGATIVE FEEDBACK

The basic self-saturating push-pull circuit[34] which may be employed either with a-c load or with d-c load, contains only four half-wave rectifier elements. In the typical example of Fig. 3, the two equally rated saturable-reactor systems (the plus-minus system and the minus-plus system) with gate windings N_A, d-c control windings N_C, and d-c differential-feedback windings N_F (providing magnetic negative feedback) are combined by means of a power-supply transformer T_P with a center-tapped secondary winding. The resultant voltage drop (load voltage) E_L across series-mixing resistors R_E', R_E'' is proportional to the actual resultant output current $(I_L'-I_L'')$, where $I_L'=I_1+I_2$, and $I_L''=I_3+I_4$. Quiescent-current values are conveniently adjusted with parallel resistors, R_1 to R_4, across silicon diodes, D_1 to D_4. Actual values of ampere-turn gain K_{AT} (equations 1 to 4) and over-all volts-per-turn gain (equations 5 and 6) may be easily adjusted within large ranges as required, by varying the negative-feedback control resistor R_F; i.e., by varying the ampere-turn ratio $(I_FN_F)/(I_SN_C)$. In this way it is possible to vary the effective feedback factor, which is a measure for the stability of operation (drift).

The graphical symbols of Fig. 3 show that the black rectifiers, D_1 and D_3, are conducting simultaneously during the first half-cycle period of power-supply voltage E_P (black polarities), while the white rectifiers, D_2 and D_4, conduct simultaneously during the second half-cycle period of E_P (white polarities). Fig. 4 shows the variations of the average values of the four half-cycle pulses, I_1 to I_4, and the waveforms of the resultant full-wave unidirectional output currents I_L', I_L'', and $I_L'-I_L''$ for the typical example that, with no-signal conditions $(E_S=0)$, the pulses I_1 to I_4 have 50% of their maximum value; i.e., the firing angle of the four saturable-reactor elements is 90 degrees.

Evidently, with $E_S=0$, the average values of the first-half-cycle pulses, I_1 and I_3, and those of the second-half-cycle pulses, I_2 and I_4, are equal, and $I_L'-I_L''$ is zero. When a positive signal voltage, $+E_S$, is applied, the firing angles of I_1 and I_2 decrease, while those of I_3 and I_4 increase. However, when a negative signal voltage, $-E_S$, is applied, the firing angles of I_1 and I_2 increase, while those of I_3 and I_4 decrease. Thus, the resultant unidirectional full-wave output voltage $E_L=I_LR_L=\text{constant}\times(I_L'-I_L'')$ is polarity-reversible and is zero at zero input.

The magnetic-negative-feedback circuit of Fig. 3, which may be employed in the output stage of magnetic-amplifier-operated ink recorders, will serve as a demonstration of half-cycle response and its relationships to gain characteristics. This fundamental arrangement has been investigated using the simple test circuit of Fig. 2, in which a synchronous unidirectional square-wave signal voltage (E_S) derived from a ferroresonant square-wave generator with phase shifter is applied to the input circuit of the magnetic amplifier under test. Fig. 5 shows the waveform of the 400-cycle signal voltage $E_S=I_SR_S$ which is synchronous with the 400-cycle power-supply voltage E_P of the push-pull amplifier (Fig. 3).

When performing these measurements, the circuit parameters $(R_S, N_C, \text{and } R_F)$ and the angular position of the rotor of the phase shifter are adjusted always in such a way that the half-cycle-response output-voltage waveform, as schematically indicated by the upper trace of Fig. 1(B), is obtained. Fig. 6 illustrates this procedure in the typical case that the number of turns of control-winding units N_C and negative-feedback-winding units N_F are constant, whereas the series resistor R_S is varied (in the vicinity of correct adjustment) within certain limits: (1) Besides the first-half-cycle pulses (I_1 and I_3), there still are second-half-cycle pulses (I_2 and I_4) of greatly reduced amplitude, i.e., the resistance R_S is too small. (2) There are only first-half-cycle pulses, and the second-half-cycle pulses disappear (half-cycle response condition); i.e., the resistance R_S has the correct value. (3) Besides the first-half-cycle pulses (I_1 and I_3), there are smaller second-half-cycle pulses (I_2 and I_4) of negative polarity; i.e., the resistance R_S is too large.

Using this method for establishing half-cycle-response operating conditions of the push-pull circuit of Fig. 3, the parameters $R_S=E_S/I_S$, N_C, and R_F have been varied. The average values of signal voltage E_S, signal current I_S, and load voltage E_L are measured by means of high-precision moving-coil instruments.

diameter = $1^3/_8$ inches; tape width = 1/4 inches), and with

$E_P=E_P'=E_P''=115$ volts ($f_P=400$ cps); $N_A=1{,}600$ turns;

$N_C=100$, 150, 200, 300, or, 400 turns; i.e., $N_A/N_C=16.0$, 10.7, 8.0, 5.3, or 4.0, respectively;

$N_F=50$ turns; $R_E'=R_E''=1{,}000$ ohms; $R_L=10{,}000$ ohms; $R_S=E_S/I_S=300\ldots3{,}000$ ohms.

There is a linear relationship between average values of E_S and E_L. The linearity error; i.e., the deviation of the actual output-input characteristic from the ideal linear characteristic $E_L=f(E_S)$ is of the order of $\pm1\%$ of full-scale deflection of the output voltmeter ($R_L=10{,}000$ ohms), which represents the load in the test circuit, where no additional load has been used.

Fig. 7(A) shows the usable voltage gain E_L/E_S as a function of turns ratio N_A/N_C with input resistance R_S as a parameter. This presentation makes it evident that, within certain limits (e.g., with $R_S=1{,}000$ ohms, and $N_A/N_C=5.3$ to 16.0), approximately the same voltage gain (about 3.3 to 3.8) can be obtained with different values of N_A/N_C by proper adjustment of the negative-feedback control resistor R_F. In order to obtain higher values of voltage gain E_L/E_S, the turns ratio N_A/N_C must be increased, and input resistance R_S must be reduced.

Fig. 7(B) shows the transresistance E_L/I_S as a function of N_A/N_C with R_S as a parameter. Within certain limits; e.g., with $R_S=1{,}000$ ohms, and $N_A/N_C=5.3$ to 16.0, approximately the same value of E_L/I_S (about 3.4 to 4.0) can be obtained by proper adjustment of the negative-feedback control resistor R_F. In order to obtain higher values of transresistance E_L/I_S, the turns ratio N_A/N_C must be reduced, and input resistance R_S must be increased.

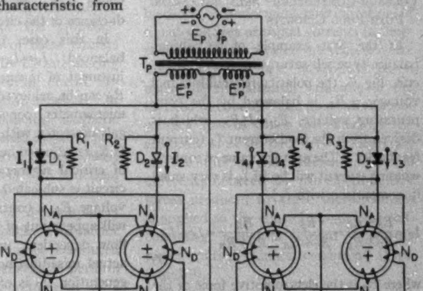

Fig. 9. Voltage-controlled self-balancing push-pull circuit with voltage feedback. The voltage ratio of this circuit is $E_L/E_S=(R_1+R_2)/R_1$

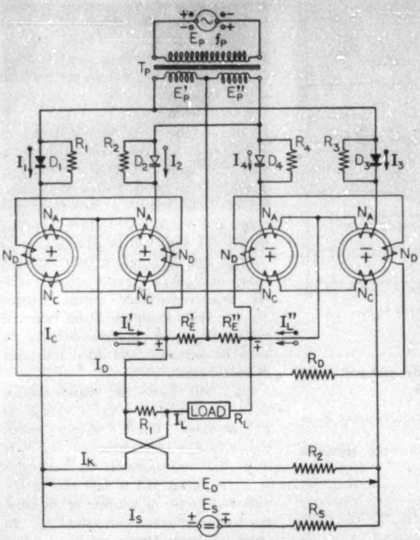

Fig. 10. Current-controlled self-balancing push-pull circuit with current feedback. The current ratio of this circuit is $I_L/I_S=(R_1+R_2)/R_1$

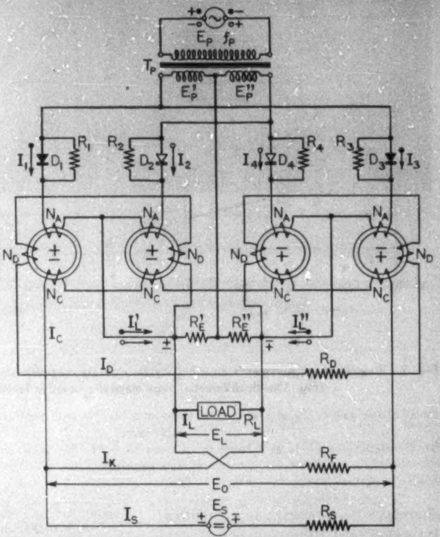

Fig. 11. Current-controlled self-balancing push-pull circuit with voltage feedback. The transresistance of this circuit is $E_L/I_S=R_F$

VOLTAGE-CONTROLLED SELF-BALANCING PUSH-PULL CIRCUITS

In the first example of a voltage-balance-type self-saturating push-pull circuit, Fig. 8, the polarity-reversible signal voltage, $\pm E_S$, is balanced by the compensating voltage, $E_K=I_LR_K$, which is derived from the load current I_L (current feedback). The average value of control-winding current will be (if I_C is very small in comparison with I_L)

$$I_C=\frac{E_S-E_K}{R_C+R_K}=\frac{E_S}{R_C+R_K}-\frac{E_K}{R_C+R_K}=I_S-I_K \tag{7}$$

where E_S is the electromotive force of the d-c signal source, and R_C is the total resistance of the control circuit between the terminals of negative-feedback resistor R_K (including the sum of the resistances of the control-winding units N_C, and the internal resistance of the signal source). The term $I_S=E_S/(R_C+R_K)$ is the signal-current component, and $I_K=E_K/(R_C+R_K)$ is the compensating-current componet. It has been shown[4] that with critical regeneration (infinite internal gain of the amplifier) the relationship between average value of load current I_L and signal voltage E_S is

$$\frac{E_S}{I_L}=R_K \quad\text{or}\quad \frac{I_L}{E_S}=\frac{1}{R_K} \tag{8}$$

where $1/R_K$ represents the transconductance of the circuit.

In this case, the control circuit is balanced: $I_C=I_S-I_K=0$. Proper adjustment of regeneration-control resistor R_D can be achieved easily by means of a microameter consisting of a lightspot galvanometer with low-resistance shunt: If R_D is adjusted below or above the point of critical regeneration while the input circuit is subjected to variations of signal voltage E_S, a control-winding current I_C will appear but of a direction of current flow dependent upon the direction of actual misadjustment. With critical regeneration, I_C is of the order of $0.001\times I_L$, and the signal voltage E_S has only a transient effect upon the magnetic amplifier.

When deriving the compensating voltage, E_K, from the load voltage (voltage feedback), the relationship between average value of load voltage E_L and signal voltage E_S is given by the resistance ratio of a voltage divider, as illustrated in Fig. 9:

$$\frac{E_L}{E_S}=\frac{R_1+R_2}{R_1} \tag{9}$$

where $(R_1+R_2)/R_1=K_E$ is the voltage ratio or voltage gain of the amplifier.

CURRENT-CONTROLLED SELF-BALANCING PUSH-PULL CIRCUITS

Fig. 10 shows a current-balance-type self-saturating push-pull circuit, in which the polarity-reversible signal current, $\pm I_S$, is balanced or "bucked out" by a compensating current I_K. In this arrangement, I_K is derived from the load current I_L (current feedback). With critical regeneration, the relationship between I_L and I_S is

$$\frac{I_L}{I_S}=\frac{I_L}{I_K}=\frac{R_1+R_2}{R_1} \tag{10}$$

where $(R_1+R_2)/R_1=K_I$ represents the current ratio or current gain of the amplifier.

In the modified arrangement of Fig. 11, the compensating current I_K is derived from the load voltage E_L (voltage feedback). The relationship between E_L and I_S is

$$\frac{E_L}{I_S}=\frac{E_L}{I_K}=R_F \tag{11}$$

where R_F is the transresistance of the circuit.

COMPARISON OF THE DIFFERENT FORMS OF SELF-BALANCING PUSH-PULL CIRCUITS

The adaptability of these circuits in conjunction with magnetic-amplifier-operated ink recorders with regard to various problems in instrumentation and telemetering may be judged by considering their specific technical properties which may be summarized as follows.

In all cases, the external gain of the system (transconductance, voltage ratio, current ratio, or transresistance, respectively) is substantially independent of large changes in the internal gain of the amplifier itself; and in all cases, effective resistance values of both input and output circuit are influenced by the very large amount of electric negative feedback in a way which is advantageous with regard to practical applications of such arrangements. There are, however, basic differences between the specific properties of the various forms of these self-balancing magnetic amplifiers, as illustrated in the typical examples of Figs. 8 to 11. These differences result from the different forms of negative-feedback networks and may be summarized in the following statements:

1. In voltage-balance amplifiers, Figs. 8 and 9, the effective input resistance E_S/I_C is greatly increased, and no appreciable current, I_C, is drawn from the signal source. These amplifiers act like a voltmeter having a very high resistance.
2. In current-balance amplifiers, Figs. 10 and 11, the effective input resistance E_O/I_S is greatly reduced, and no appreciable voltage drop, E_O, is introduced into the circuit under test. These amplifiers act like an ammeter having a very low resistance and a very small voltage drop across its terminals.
3. In voltage-output amplifiers, Figs. 9 and 11, utilizing voltage feedback, the effective internal resistance of the output circuit is greatly reduced. These amplifiers act like a low-impedance generator; and actual magnitude of output voltage, E_L, is substantially independent of large changes in load resistance R_L.
4. In current-output amplifiers, Figs. 8 and 10, utilizing current feedback, the effective internal resistance of the output circuit is greatly increased. These amplifiers act like a high-impedance generator; and actual magnitude of output current, I_L, is substantially independent of large changes in load resistance R_L.

It has been stressed already that the relationship between power gain, linearity error, and response time is such that if one property is accentuated, it is always at the expense of the other properties. Although the external gain of a self-balancing magnetic amplifier is independent of the number of turns of the control windings N_C, Figs. 8 to 11, it is generally desirable, in the interest of optimum linearity, to provide as many turns as the required response time will permit. In this way the inevitable residue of compensating ampere-turns which must be supplied by the control circuit will require a minimum of current from that source, resulting in a minimum linearity error. Furthermore, the use of the greatest possible number of turns of the control windings N_C has the important added advantage of improving the stability of the amplifier by providing for a maximum of negative-feedback ampere-turns.

On the other hand, actual response time of self-balancing magnetic amplifiers may be reduced to its minimum value of one half-cycle of the power-supply frequency, as characterized in Figs. 1 and 6. Analysis of the voltage-balance form of this amplifier[36] reveals that half-cycle response will be obtained if turns ratio N_A/N_C of self-saturating circuits (Figs. 8 to 11) is approximately equal to the resistance ratio R_O/R_K, where R_K is the actual resistance of the negative-feedback resistor, and R_O is the total resistance of the output circuit including the load-resistance components, copper resistance of the gate windings N_A, and forward resistance of the rectifiers, D_1 to D_4. Analysis of the current-balance form[36] of the self-balancing magnetic amplifier reveals similar relationships.

It is possible to apply nonlinear circuit elements; e.g., thermo converters, in the negative-feedback channel of the circuits of Figs. 8 to 11 to obtain special output-input characteristics of the amplifier. The transient response of these circuits may be altered materially by introducing differentiating or integrating circuit elements into the degeneration network. In this case, the self-balancing magnetic amplifier imposes its special dynamic performance characteristics on the associated system (e.g., ink recorder) with beneficial results. In accordance with common practice in the field of d-c amplifiers utilizing negative feedback, a capacitor or a mutual inductance may be introduced into the degeneration network to perform the integration or differentiation of a variable directly with respect to time.[37]

Algebraic Summation and Multiplication of Signals with Magnetic-Amplifier-Operated Ink Recorders

General

One of the more important advantages of magnetic amplifiers for instrumentation resides in the fact that complete isolation is possible between input and output. Such amplifiers are well suited to perform mixing of several d-c control signals at different voltage levels. Over the linear range of the output-input characteristic the output is proportional to the algebraic summation of signals. Thus, an obvious method to perform multiplication of signal voltages or signal currents consists in applying two thermocouples, one of which is heated by the algebraic sum of two derived currents and the other, by their difference. Insulated-heater-type thermo converters, however, are rather slow in response. Therefore, the use of such forms of thermocouples for this purpose is associated with an appreciable time lag (about 3 to 5 seconds) which may be permissible in some cases. When employing high-speed thermo converters,[38] e.g., special constructions of thermocouples, as used in high-speed thermal wattmeters,[39] a response time of the order of one-half second can be obtained.

L. A. Finzi and R. A. Mathias[40] have shown that it is possible to perform multiplication and other analytical operations by means of special magnetic-amplifier circuits, the components of which are single-core half-wave amplifiers of the kind described by R. A. Ramey.[41] The operation of these multiplying circuits, however, involves the basic assumption that each of the two signal voltages has a certain polarity which does not change. Otherwise, the circuits become inoperative.

In the following sections, two novel methods of performing multiplication of signal voltages or signal currents in magnetic-amplifier-operated ink recorders are described. The first method is based upon the fundamental principle of the thermal wattmeter[42] and uses two thermocouples, one of which is heated by the algebraic sum of two derived currents, and the other, by their difference. Actual difference between the two electromotive forces produced by these thermocouples is applied to the control circuit of a self-balancing push-pull circuit operating under voltage-balance conditions (Figs. 8 and 9).

The second method consists in replacing the two thermocouples by two special magnetic-amplifier multiplying circuits, which act as square-law means and provide the square term of the algebraic sum of two derived currents, and the square term of their difference, respectively. This method does not involve any assumptions on actual polarities of the two signal voltages or signal currents to be multiplied; i.e., each of the two d-c signals may change its polarity without any restrictions. This performance is one of the basic requirements of these instrumentation problems, which are concerned with multiplication of polarity-reversible d-c signal voltages or signal currents.

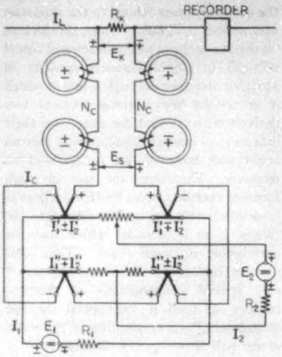

Fig. 12 (left). Multiplication of signal currents I_1 and I_2 by means of a symmetrical Wheatstone-bridge circuit with two pairs of insulated-heater-type thermo converters, and a self-balancing magnetic amplifier operating under voltage-balance conditions

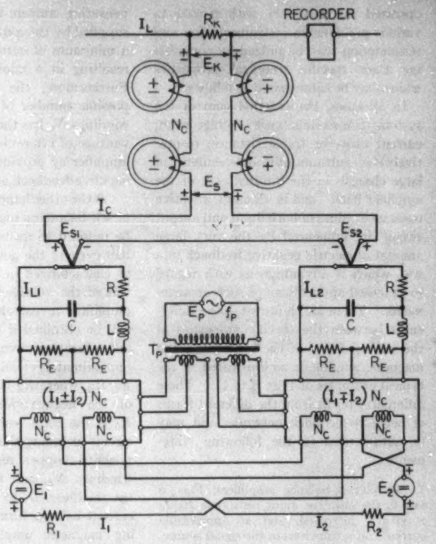

Fig. 13 (right). Multiplication of signal currents I_1 and I_2 by means of two directly heated thermal converters and two magnetic-amplifier push-pull circuits, which are controlled by (I_1+I_2) and (I_1-I_2) respectively

MULTIPLICATION OF SIGNALS WITH THERMOCOUPLES AND SELF-BALANCING MAGNETIC AMPLIFIER

Multiplication of signals with thermocouples is the fundamental principle of thermal wattmeters for measurement of power at frequencies above the conventional design range of electromagnetic instruments. In such arrangements, two thermocouples (or two groups of series-connected thermocouples) are employed, one of which is heated by the algebraic sum of two derived currents (I_1+I_2) and the other, by their difference (I_1-I_2). The quantity of heat produced in the two heaters of the thermal converters, assuming the heater resistance R_H to remain constant, is $R_H(I_1+I_2)^2$, and $R_H(I_1-I_2)^2$, respectively. With proper design, the temperature rise of the heated member is very closely proportional to the quantity of heat produced in it. Thus, when connecting the terminals of the two thermocouples in opposition, a d-c signal voltage, E_S, can be obtained, which is linearily proportional to the actual difference between the temperatures of the two heaters:

$$E_S=K'(I_1+I_2)^2-K''(I_1-I_2)^2 \qquad (12)$$

If the constants K' and K'' are equal, then

$$E_S=\text{const}\times[(I_1^2+2I_1I_2+I_2^2)-(I_1^2-2I_1I_2+I_2^2)] \qquad (13)$$

or

$$E_S=\text{const}\times 4I_1I_2 \qquad (14)$$

Because the square terms cancel in this case, the d-c signal voltage E_S, indicated by an ordinary moving-coil millivoltmeter, is linearily proportional to the product $I_1\times I_2$ to be measured.

It has been stressed previously[4,33] that voltage-balance-type self-balancing magnetic amplifiers are particularly well suited for measuring small d-c millivoltages created by thermocouples or radiation pyrometers. In the present application, this type of magnetic amplifier has been employed in conjunction with a standard-type moving-coil ink recorder for measuring and recording the d-c signal voltage $E_S=\text{const}\times I_1\times I_2$ (equation 14). Fig. 12 shows a symmetrical Wheatstone-bridge circuit with two pairs of insulated-heater-type thermo converters, one of which is heated by the algebraic sum of currents

$$(I_1'\mp I_2')=(I_1''\mp I_2'')=0.5(I_1\mp I_2) \qquad (15)$$

and the other, by the difference of these currents

$$(I_1'\pm I_2')=(I_1''\pm I_2'')=0.5(I_1\pm I_2) \qquad (16)$$

The individual currents $I_1=\text{const}\times E_1$ and $I_2=\text{const}\times E_2$ to be multiplied are led to equipotential terminals of the bridge network to secure proper distribution of current components, as defined by equations 15 and 16.

The resultant polarity-reversible d-c signal voltage E_S (equation 14) produced by the series-opposing-connected pairs of thermocouples (Fig. 12) is balanced by the voltage drop $E_K=I_LR_K$ across negative-feedback resistor R_K of the self-balancing magnetic amplifier of Fig. 8. Thus, there is a linear relationship between $E_S=E_K$ and the average value of polarity-reversible load current I_L flowing through the ink recorder:

$$I_L=\text{const}\times I_1\times I_2=\text{const}\times E_1\times E_2 \qquad (17)$$

It is to be noted, however, that insulated-heater-type thermo converters, as used in the bridge circuit of Fig. 12, are rather slow in response, actual response time being about 3 to 5 seconds. Although such slow-response performance may be acceptable in some cases, it will prevent proper recording of phenomena acting at a moderately rapid rate. Considerably faster response, of the order of 1 or 2 seconds, can be obtained by using directly-heated high-speed thermo converters, or a special construction, where the thermocouples function also as heaters.[39] With this arrangement, response time of the order of one-half second is obtained.

Application of directly heated thermo converters is associated with the basic requirement that the heaters of the two thermocouples are insulated from each other. The arrangement of Fig. 13 meets this requirement by providing two magnetic-amplifier push-pull circuits, the control-winding units N_C of which are insulated from the two output circuits being also insulated from each other (by means of two separate center-tapped secondary

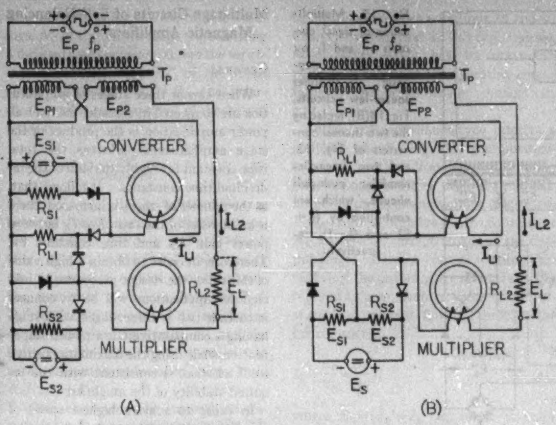

Fig. 14. Basic forms of magnetic-amplifier multiplying circuits

A—Original circuit which multiplies two d-c signal voltages E_{S1} and E_{S2} (Finzi and Mathias[40])
B—Modified circuit, which multiplies the components $E_{S1}=E_{S2}=0.5\times E_S$ of a single d-c signal voltage E_S, and may be used for providing square terms of signal voltages and signal currents (square-law-circuit output voltage $E_L=\text{constant}\times E_S^2$)

windings of a common power-supply transformer). Actual magnitudes of output currents I_{L1} and I_{L2} depend here on the total magnetomotive force of control produced jointly by the input windings N_C carrying currents $I_1=E_1/R_1$ and $I_2=E_2/R_2$, respectively. In this case,

$$I_{L1}=\text{const}\times(I_1\pm I_2)N_C \tag{18}$$

and

$$I_{L2}=\text{const}\times(I_1\mp I_2)N_C \tag{19}$$

where I_{L1} and I_{L2} are the average values of the two output currents. The two filter circuits are provided to secure that the rms values of heater currents are substantially equal to the average values of I_{L1} and I_{L2}. If this condition is fulfilled; i.e., if the a-c components of I_{L1} and I_{L2} are reduced to be only about 2 to of 3% the associated d-c components, then

$$E_{S1}=\text{const}\times I_{L1}^2=\text{const}\times(I_1\pm I_2)^2 \tag{20}$$

and

$$E_{S2}=\text{const}\times I_{L2}^2=\text{const}\times(I_1\mp I_2)^2 \tag{21}$$

The resulting d-c signal voltage

$$E_S=E_{S1}-E_{S2}=\text{const}\times I_1I_2 \tag{22}$$

is balanced by the voltage drop $E_K=I_LR_K$ across negative-feedback resistor R_K of a self-balancing push-pull circuit (Fig. 8). In this case, too, there is a linear relationship between $E_S=E_K$ and the average value of the polarity-reversible load current I_L flowing through the ink recorder:

$$I_L=\text{const}\times I_1\times I_2=\text{const}\times E_1\times E_2 \tag{23}$$

The accuracy of these thermal methods (Figs. 12 and 13) to perform multiplication of signals is such that the differences between the actually indicated values and those corresponding to an ideal performance characteristic (equation 23) is about ±2 to 3% of full-scale deflection of the ink recorder. This accuracy is considered to be sufficient for many applications. There is, of course, still a basic limitation which is caused by the relatively slow response of thermal converters (minimum response time about one-half of one second).

Multiplication with Magnetic Amplifiers and Magnetic-Amplifier Square-Law Circuits

In order to make operation of such multiplying devices in conjunction with an ink oscillograph (e.g., Brush recorder) possible, the two thermocouples of Fig. 13 have been replaced by two special magnetic-amplifier multiplying circuits, which act as square-law means and provide the square term of the algebraic sum of two derived currents, and the square term of their difference, respectively. In this arrangement, full advantage is taken of the half-cycle-response characteristics of Ramey-type single-core half-wave magnetic amplifiers, and full-wave push-pull circuits (Figs. 3 and 8) utilizing a very large amount of negative feedback.

The magnetic-amplifier multiplying circuit, Fig. 14(A), as described by Finzi and Mathias,[40] is basically a 2-stage arrangement, which contains the converter (input stage controlled by the first signal voltage E_{S1}), and the multiplier (output stage controlled by the second signal voltage E_{S2}). Resistors R_{S1} and R_{S2} provide the necessary path for the presetting magnetizing currents flowing against the signal voltages. Operation of the circuit of Fig. 14(A) can be described by the equation

$$E_L=I_{L2}R_{L2}=\text{const}\times\frac{E_{S1}\times E_{S2}}{E_{P1}} \tag{24}$$

where E_{S1} and E_{S2} represent average values, and E_{P1} is the rms value of supply voltage E_{P1} derived from the power-supply transformer T_P having two separate secondary windings. With $E_{P1}=$ constant, there is the simplified relationship

$$E_L=\text{const}\times E_{S1}\times E_{S2} \tag{25}$$

Proper operation of this multiplying circuit, however, involves certain requirements, which may be summarized as follows:

1. In each stage, the gate voltage (E_{P1} and E_{P2}, respectively) must satisfy the condition: $E_{P\max}<\omega N\Phi_{\text{sat}}$, where $\omega=2\pi f_P$ is the angular velocity of the a-c power supply (frequency f_P), N is the number of turns of the cores, and Φ_{sat} is the saturation flux density of the rectangular-hysteresis-loop core material.

2. Certain limitations with regard to the relationships between the instantaneous values of signal voltages E_{S1}, E_{S2}, and gate voltages E_{P1}, E_{P2} require that E_{P1} and E_{P2} must be square waves symmetrical about zero (as obtained from a d-c power source through a rotating commutator[40]) if E_{S1} and E_{S2} are pure d-c signal voltages (as derived from battery or filter circuits).

3. In both stages, the magnetizing currents must be minimized by proper design of the high-permeability cores. Since the magnetomotive force required by a core over intervals of increasing or decreasing fluxes is practically constant, a large part of it may be provided by an auxiliary winding fed from a synchronous compensating current[40] which is derived from the same power supply (E_P).

4. Each of the two d-c signal voltages, E_{S1} and E_{S2}, has a certain polarity (with regard to the half-wave rectifier elements series-connected with the resistors R_{S1} and R_{S2}), which does not change. Otherwise, the circuit becomes inoperative.

However, one of the basic requirements in many problems concerning multiplication of d-c signals is that each signal may change its polarity. In order to fulfill

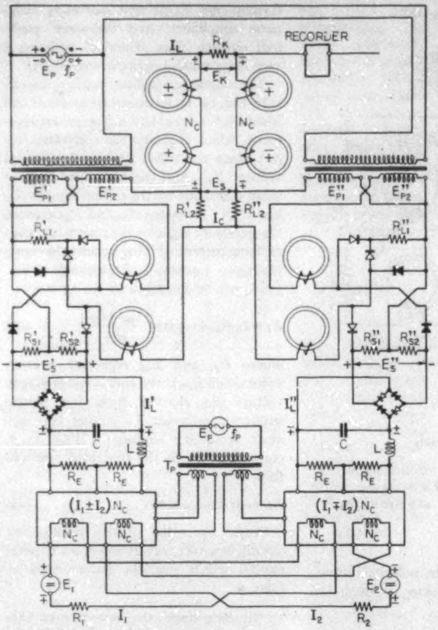

Fig. 15. Multiplication of signal currents I_1 and I_2 by means of two magnetic-amplifier square-law circuits, Fig. 14(B), replacing the two thermal converters of Fig. 13, and two magnetic-amplifier push-pull circuits, which are controlled by (I_1+I_2) and (I_1-I_2), respectively

this requirement, the two thermocouples in the arrangement of Fig. 13 have been replaced by two magnetic-amplifier square-law circuits, as shown in Fig. 14(B). The applied modification consists merely in supplying the two signal circuits from a center-tapped input resistor $(R_{S1}+R_{S2})$ so that $E_{S1}=E_{S2}=0.5\,E_S$. In this case, too, the signal voltage E_S must have a certain polarity, as indicated in Fig. 14(B). Otherwise, the circuit becomes inoperative.

In the complete arrangement of Fig. 15, the two magnetic-amplifier square-law circuits, Fig. 14(B), provide the square term of the algebraic sum of the currents $I_1=E_1/R_1$ and $I_2=E_2/R_2$, as well as the square term of the difference of these currents:

$$E_L'=\text{const}\times(I_L')^2=\text{const}\times(I_1\pm I_2)^2 \quad (26)$$

and

$$E_L''=\text{const}\times(I_L'')^2=\text{const}\times(I_1\mp I_2)^2 \quad (27)$$

Filter circuits L, C, and full-wave rectifiers across mixing resistors R_E (Fig. 3) are provided to convert the polarity-reversible output currents $I_L'=\text{const}\times(I_1+I_2)$ and $I_L''=\text{const}\times(I_1\mp I_2)$ of the two magnetic-amplifier push-pull circuits into substantially pure direct currents, which do not change their polarity.

The arrangement of Fig. 15 has been used in conjunction with a Brush recorder making a permanent record of the product of currents $I_1=0\pm50$ μa, and $I_2=0\pm50$ μa ($R_1=R_2=50{,}000$ ohms). When supplying the two magnetic-amplifier square-law circuits, Fig. 14(B), from a ferroresonant circuit or from a switching-transistor d-c to a-c converter ($f_P=400$ cps), the gate voltages (E_P) are symmetrical square waves symmetrical about zero; and pure d-c signal voltages E_S' and E_S'' can be applied in this case without disturbing proper operation of these circuits. Supermalloy 2-mil tape cores have been used successfully to minimize the magnetizing currents. Five silicon junction diodes in each circuit are connected, as shown in Figs. 14(B) and 15. The accuracy of measurements obtained with this arrangement (about ±2 and 3% of full-scale deflection of the ink oscillograph) was sufficient in the respective application, where high-speed operation (the response time is of the order of about 2 cycles of the power-supply frequency; i.e., about 5 msec) of the recorder is of major importance.

Multistage Circuits of Self-Balancing Magnetic Amplifiers

GENERAL

When two or three stages of amplification are connected in cascade, the over-all power amplification is the product of the stage amplifications, whereas the total time constant is roughly the sum of the individual time constants. It follows that, as the number of stages is increased, there is an increase of the ratio K_P/T_C between power gain K_P and time constant T_C. Therefore, in order to obtain a high value of this ratio, the design procedure in ink-recorder applications will be to connect in cascade two or three stages, each stage having a comparatively low power amplification while using the maximum positive feedback that is consistent with the required stability of the amplifier.

In order to achieve highest speed of response in multistage push-pull circuits, the parameters of each stage (Figs. 3, and 8 to 11) will be rated so that half-cycle response (Fig. 6) is obtained. When using several half-cycle-response full-wave push-pull circuits in cascade, the over-all response time is one half-cycle for first stage, and one half-cycle for each additional stage. Thus, the over-all response time of a 2-stage arrangement is one cycle and that of a 3-stage design is $1^1/_2$ cycles. In this way, with 400-cycle-operated multistage magnetic-amplifier circuits, an over-all response time of the order of 3 to 4 msec can be achieved.

INTERSTAGE COUPLING CIRCUITS

The various possibilities for connecting push-pull self-saturating circuits, Fig. 3, and Figs. 8 to 11, in cascade may be illustrated with regard to a 2-stage design, by three typical examples (Figs. 16 to 18). In the simplest form of interstage

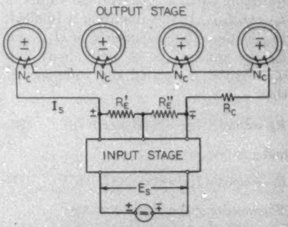

Fig. 16. Simplest form of interstage coupling circuit, in which the control windings N_C of the output stage are connected across the series-mixing resistors R_E', R_E'' of the input stage. The current ratio of this circuit is $I_S/(I_L'-I_L'')=R_E/(2R_E+R_C)$

coupling circuit, Fig. 16, the control windings, N_C of the output stage (representing a d-c load) are connected across the series-mixing resistors R_E', R_E'' of the input stage. With $R_E'=R_E''=R_E$, the polarity-reversible signal current of the output stage is

$$I_S=(I_L'-I_L'')\ \frac{R_E}{2R_E+R_C} \tag{28}$$

where $(I_L'-I_L'')$ is the actual difference between average values of resultant output currents $I_L'=I_1+I_2$ and $I_L''=I_3+I_4$ (Fig. 4). R_C is the total resistance of the output-stage control circuit between the terminals of mixing resistors R_E', R_E'' (including the sum of the resistances of the control-winding units N_C, and the series resistor, which may be omitted to obtain maximum value of resistance ratio $R_E/(2R_E+R_C)$.

When employing the current-balance-type interstage coupling circuit, Fig. 17, the control-winding current $I_C=I_S-I_K$ is substantially reduced to zero. Thus, actual voltage drop, E_O, across series-mixing resistors R_E', R_E'' is also substantially reduced to zero:

$$E_O=I_CR_N=(I_S-I_K)R_N=0 \tag{29}$$

In this case, the output-stage control circuit acts like an ammeter without voltage drop across its terminals; and the effective resistance of this control circuit is practically about 100 to 1,000 times smaller than actual resistance (R_N) of the four series-connected control-winding units (N_C). Consequently, with $E_O=0$,

$$I_S=0.5(I_L'-I_L'') \tag{30}$$

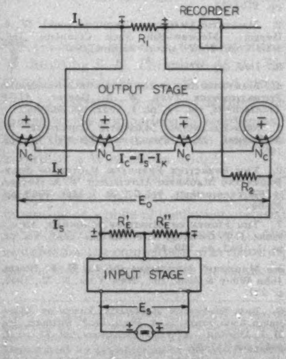

Fig. 17. Current-balance-type interstage coupling circuit, in which the control-winding current, $I_C=I_S-I_K$, of the output stage is substantially reduced to zero. The current ratio of this circuit is $I_S/(I_L'-I_L'')=0.5$

Comparison between equations 28 and 30 makes it evident that, in this case, current ratio $I_S/(I_L'-I_L'')$ has its maximum value with regard to the operating conditions of the series-resistor mixing circuit.

In the voltage-balance-type interstage coupling circuit, Fig. 18, the polarity-reversible voltage drop $E_L=f(E_S)$ across series-mixing resistors R_E', R_E'' is balanced by the opposing voltage drop $E_K=I_LR_K$ across negative-feedback resistor R_K in the load-current circuit of the output stage. Because control-winding current I_C of the output stage is substantially reduced to zero, average value of output-stage load current flowing through the ink recorder is

$$I_L=\frac{E_K}{R_K}=\frac{E_L}{R_K} \tag{31}$$

where $E_L=(I_L'-I_L'')R_E$ is the average value of output voltage of the input stage.

In all cases, Figs. 16 to 18, the input stage may operate as a self-balancing circuit under either voltage-balance (Figs. 8 and 9) or current-balance (Figs. 10 and 11) conditions. When employing multistage push-pull circuits to perform multiplication of signals, a magnetic-negative-feedback input-stage circuit with two separate groups of control windings (Figs. 13 and 15) will be used.

Applications and Performance Characteristics of Magnetic-Amplifier-Operated Ink Recorders

General

The high sensitivity of Esterline-Angus permanent-magnet moving-coil ink recorders permits in many cases direct operation of these instruments without the use of amplifiers. There are two basic sensitivities, 0–1 ma (resistance, 1,400 ohms), and 0–5 ma (resistance, 70 ohms), either type completing its swing across the $4^1/_2$-inch active chart width in about 1/2 second with critical-damping conditions.[43]

In order to extend the range of application of these instruments, a simple and reliable d-c amplifier will be required. With regard to the moderate response properties of such recorders, a 60-cycle-operated magnetic amplifier with a time constant of about 100 msec is generally acceptable. The arrangement is well suited for recording of various phenomena acting at a moderately rapid rate. However, actual requirements on power gain, linearity, and stability of operation indicate that a 2-stage design with self-balancing characteristics is needed for applications, where very good zero stability is essential.

By supplying the input stage of the 60-cycle 2-stage design with Supermalloy 2-mil tape cores and silicon rectifiers from a ferroresonant constant-voltage transformer,[33] excellent stability with regard to zero drift and constant gain has been obtained. When providing the signal-voltage range 0–5 mv or 0–±2.5 mv, this design is suitable for many applications with low-impedance signal sources; e.g., thermocouples, radiation pyrometers, strain-gage or resistance-thermometer bridge circuits, bolometer arrangements, and for resistance measurements by means of constant-voltage-supplied voltage-divider and bridge networks. With the signal-voltage range 0–20 mv or 0–±10 mv, half-cycle response is achieved. Zero stability is of the order of 100 µv per 8 hours or better at room temperatures. In a special application concerning long-time reliability testing of high-sensitivity relays, a 1-ma 1,400-ohm ink recorder in conjunction with a 60-cycle 2-stage magnetic amplifier has been operated as a high-impedance d-c millivoltmeter (8,000 ohms) having the range 0–20 mv or 0–2.5 µa for full-scale deflection of the recorder.

Brush-type ink oscillographs have been operated successfully in conjunction with a 400-cycle 2-stage or 3-stage magnetic amplifier. Dynamic performance of this arrangement can be tested conveniently by means of a motor-operated switch which closes and opens periodically an auxiliary battery-supplied test circuit, from which a unidirectional square-wave signal voltage is derived. The switch in this test circuit is operated so that, with

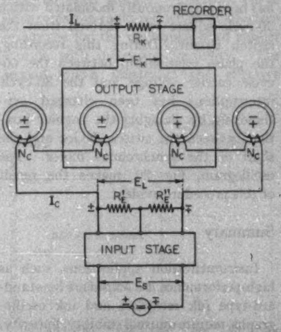

Fig. 18. Voltage-balance-type interstage coupling circuit, in which the control-winding current I_C of the output stage is substantially reduced to zero

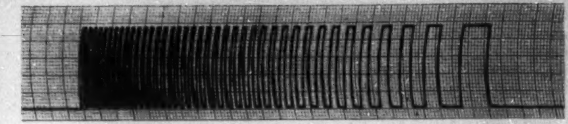

Fig. 19. Brush-recorder ink oscillogram of a 100-mv square-wave signal voltage in the frequency range from 30 cps down to d-c operating conditions. The attenuation does not exceed 5%

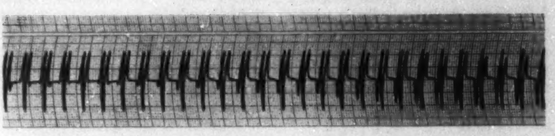

Fig. 20. Brush-recorder ink oscillogram, which has been obtained with a sinusoidal 60-cycle-carrier signal voltage being modulated with a 30-cycle square wave derived from a synchronous-motor-operated switch

full speed of the 60-cycle synchronous motor, a 30-cycle square-wave signal voltage is applied to the input circuit of the magnetic amplifier, the output current of which supplies the ink oscillograph. Then, after switching off the supply voltage of the motor, the frequency of the square-wave signal voltage is continuously reduced until the switch stops its action and remains in its open-circuit position. Fig. 19 presents an oscillogram of a 100-mv square-wave signal voltage, which has been recorded in this way.

The oscillogram of Fig. 20 shows a sinusoidal 60-cycle signal voltage, which is periodically interrupted by means of the synchronous-motor-operated switch in such a way that this voltage is turned on and off during 2 cycles, alternately. Thus, the 60-cycle-carrier signal voltage has been synchronously modulated with a 30-cycle square wave derived from the switch circuit. During this recording, the phase relationship between the 60-cycle carrier voltage and the 30-cycle interruptions has been changed continuously by changing the angular position between the switch device and the shaft of the synchronous motor. The oscillogram, Fig. 20, makes the result of this procedure evident.

Summary

Instrumentation applications, such as high-performance d-c amplifiers for standard-type ink recorders and ink oscillographs, require unusual stability, linearity, freedom from zero drift, and reliability which can be best met by an all-magnetic system using no vacuum tubes. A magnetic instrument amplifier which uses only nickel-iron-alloy tape core saturable reactor elements, silicon junction diodes, resistors, capacitors, linear reactors, and ordinary transformers can be built to meet the necessary performance requirements.

The inclusion of a multiplicity of voltage and current ranges, special control-winding arrangements, and auxiliary circuits makes magnetic-amplifier-operated ink recorders attractive for measuring signal voltages of the order of 10 to 100 mv, and signal currents of the order of 2 to 50 μa. This is possible without impairing accuracy and dynamic performance of such recorders.

Magnetic-amplifier-operated ink recorders are also well suited to perform mixing of signals; i.e., algebraic summation of signal voltages and signal currents. Multiplication of signals may be performed by means of two thermocouples, one of which is heated by the algebraic sum of two derived currents and the other, by their difference. Another possibility to perform multiplication consists in replacing the two thermocouples by two magnetic-amplifier multiplying circuits, which act as square-law means and provide the square term of the algebraic sum of two derived currents, and the square term of their difference, respectively.

Magnetic amplifiers of the self-balancing potentiometer type operating under either voltage-balance or current-balance conditions in conjunction with ink recorders offer important advantages with regard to power gain and dynamic performance. With proper design of these self-balancing magnetic amplifiers having infinite internal gain (critical regeneration) and utilizing a very large amount of electric negative feedback, resistance-coupled into the control-circuit loop, actual response time of the amplifier can be reduced to one half-cycle of the power-supply frequency. Thus, when using a 400-cycle power supply, the amplifier does reach 100% of its final steady-state output current 1.25 msec after the transient signal voltage is applied; and the output current drops to zero 1.25 msec after the signal voltage is suddenly removed.

A Brush recorder operating with a 400-cycle-operated 2-stage or 3-stage self-balancing magnetic amplifier (each stage having half-cycle response) has been used for recording 30-cycle signals with attenuation not exceeding 5%. The dynamic performance of this arrangement is characterized by typical ink oscillograms, which have been obtained by recording variable-frequency sinusoidal-waveshape and square-wave signals.

When employing a permanent-magnet moving-coil Esterline-Angus recorder, the response time of the 60-cycle-operated magnetic instrument amplifier of the order of 100 msec or more is permissible. This arrangement is well suited for recording of various phenomena acting at a moderately rapid rate. For long-time reliability testing of high-sensitivity relays, a 1-ma 1,500-ohm, ink recorder with a 60-cycle 2-stage self-balancing magnetic amplifier has been employed as a high-impedance d-c millivoltmeter (8,000 ohms) having the range 0–20 mv or 0–2.5 μa for full-scale deflection of the recorder.

W. H. SHIRK, JR.
NONMEMBER AIEE

THE bridge principle was first introduced by S. H. Christie in 1833. Sir Charles Wheatstone in 1843 called attention to Christie's work and applied the bridge to the comparison of resistances.[1] Since that time, the network has been known as a Wheatstone bridge.

The mechanical designs of Wheatstone bridges have followed the practice of mounting on a plate of insulating material the ratio arm blocks (plug controlled), the switches for the comparison arm rheostat, the pairs of binding posts for the unknown resistance, battery source, and galvanometer detector, as well as keys for controlling battery and detector. The most favored top plate material has been hard rubber, although Bakelite and more recent materials with dimensional stability have been tried.

The insulating properties of solid dielectrics have been studied and papers presented over the past decades.[2–4]

The insulation resistance between metal parts, such as binding post studs mounted on an insulating plate, involves simultaneous effects of both surface and volume characteristics. Moisture absorption and moisture adsorption in combination with lack of surface cleanliness are factors which influence the rapid reduction of effective insulation resistance at high relative humidities.

The papers cited, covering insulating properties of solid dielectrics, give data for many materials, and tests under various atmospheric conditions. For convenient reference, included as Fig. 1 is a graph showing insulation resistance measured between two metal binding posts mounted on 1/2-inch-thick hard rubber with a center-to-center spacing of $1^{1}/_{4}$ inches and metal-to-metal distance of 3/4 inch at the surface. The hard rubber is about 10 years old and was in raw material open storage. The first curve illustrates the rapid reduction in effective resistance for the uncleaned hard rubber sample with increasing humidity. The second curve illustrates the effective

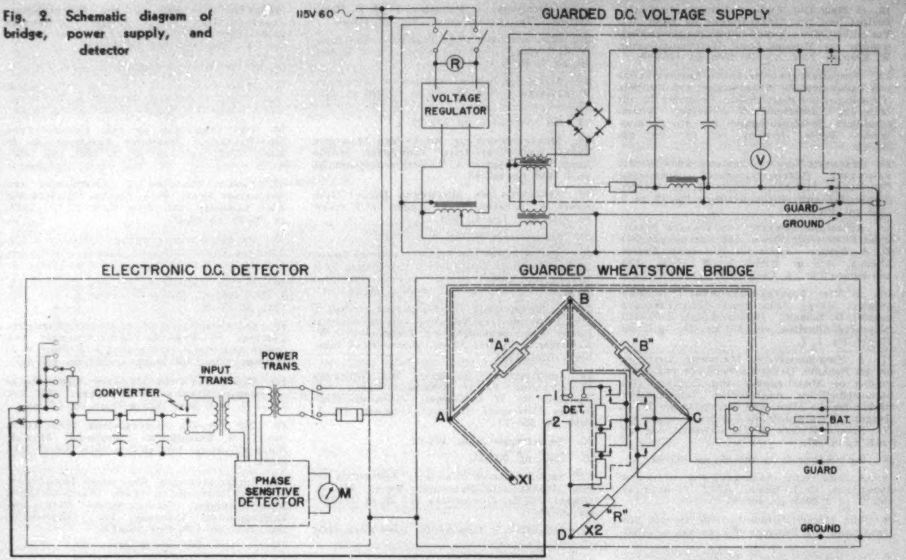
Fig. 2. Schematic diagram of bridge, power supply, and detector



resistance after cleaning and subjecting it again to several humidities.

Two points can be made from these data.

1. The graphs shown represent possible shunt resistance in parallel with the unknown resistance across the X binding posts, but this may not be the entire story as there are other shunt paths between metal parts in the network which may contribute comparable errors.

2. The degree of cleanliness of the insulation and the amount of adverse humidity may not be known, and consequently no precise corrections can be applied to the measured value of the unknown resistance.

The need for precise adjustment of resistors in the range of 100,000 ohms to 100 megohms was brought out during and subsequent to World War II. Adjustment requirements to 0.01% for absolute value and matching pairs to 0.001% with tracking to 0.01% over a wide temperature range are frequently encountered. In this paper, the discussion will be confined to measurements of resistance for absolute value with Wheatstone bridge networks and will not include discussion of ratiometers, deviation bridges, and other comparison devices.[9]

If the error in the measured value of a nominal megohm resistor will be adversely affected by the effective insulation resistance to an amount dependent upon surface condition and humidity, it is evident that some method must be devised which will limit the error due to these uncontrollable environmental conditions to permit direct reading of the unknown absolute value to high precision.

A Guarded Wheatstone Bridge

The use of guarding to control the paths of direct currents as applied to the measurement of insulation resistance is a very old technique. Texts on electrical measurements have included circuitry with guarding to measure the insulation resistance of cables, and show guard rings to divert the current over the surface at the end of the cable back to the battery so that the current measured by the detector is only that passing through the insulation of the cable between conductor and sheath.[10]

It has not been customary to use guarding for d-c Wheatstone bridges.

Consider a Wheatstone bridge network, Fig. 2, in which the X_1 binding post, the ratio arms "A" and "B", and the connection from the ratio arm junction to the detector are enclosed in a guard circuit which is permanently connected to the C corner of the bridge. The guard is also carried back to the potential supply which will be described later.

In developing the apparatus described in this paper, a design requirement was that the insulation resistance between branch points in the assembled and wired bridge should exceed the following values:

A corner to guard, 10 megohms
B corner to guard, 10,000 megohms
C corner to ground (guard to ground) 10,000 megohms

The foregoing requirements apply for environmental conditions including up to 95% relative humidity. Note that leakage current from the A corner to guard is across the bridge and merely adds load to the power supply.

The solution was to use large plugs with blocks mounted on a hard rubber plate for the ratio arms. As part of the bridge manufacturing operation, the hard rubber was cleaned and then coated with 2% Dow Corning *Z920* silicone in chemically pure carbon tetrachloride. Tests on hard rubber, so treated, measured in excess of 10×10^{12} ohms between metal parts under 95% relative humidity. The ratio block panel is enclosed in the bridge with access through a door. The vertical position of the treated hard rubber panel and the enclosure should minimize dust and moisture collecting on the panel.

The hard rubber panel is supported at the four corners with Kel-F rods which have metal caps connected to guard.

These metal caps thus provide guarding of the entire ratio arm assembly, and the Kel-F support rods provide the high insulation resistance between guard and ground.

To summarize the bridge design up to this point, a guard system has been provided with specified limits for the insulation resistance requirements for the assembled bridge for the *A*, *B*, and *C* corners. It should be noted that the *C* corner to ground (guard to ground) insulation resistance becomes a shunt across the adjustable standard "*R*". As the maximum setting for this 6-decade standard is 111,111 ohms, the requirement of 10,000 megohms minimum for *C* corner to ground under all conditions will limit this shunting error to approximately 0.001%.

The bridge corners *A*, *B*, and *C* have been discussed, but the physical arrangement for the X_1 terminal which is connected to the *A* corner has not been described. Fig. 3 shows an exploded view and an assembly of a guarded binding post. The insulating material between the center conductor and the guard is acrylonitrile-styrene copolymer which is injection molded. The metal guard shell is installed in the bridge metal top plate using two similar plastic injection molded bushings.

Measurements made on binding post assemblies similar to that shown in Fig. 3 give insulation resistance values between conductor to guard and guard to ground exceeding 10×10^{12} ohms. As this plastic has exceedingly low moisture absorption, the insulation resistance exceeds 10^{12} ohms at 95% relative humidity.[11]

There are two features of this bridge network which should be mentioned. The first feature is that the large ratio arm resistors of woven manganin webbings have low time constants, matched temperature coefficient of resistance, and sufficient wattage rating to permit testing unknown resistances at maximum voltages as outlined in *MIL-R-93A* and *R-10509-B*. Maximum military specification voltages permit the use of lower sensitivity detectors.

The second feature is that screws are provided on the ratio arm blocks to connect directly to the bridge corners *A*, *B*, and *C*. This provides a means for checking the absolute values of the ratio arms for certification and maintenance.

Requirements for Guarded Bridge Power Supply

In the precision, guarded Wheatstone bridge described here, the d-c power supply is connected through a reversing switch to the *A* and *C* corners of the bridge. It is therefore necessary to eliminate the effects of insulation resistance between the *A* bridge-corner power-supply lead and ground, otherwise this resistance will shunt the unknown resistance being measured and may result in appreciable errors when making high resistance measurements. The first requirement, therefore, is that the power supply be guarded with the guard circuit connected to the *C* corner of the bridge.

As mentioned earlier, the insulation resistance between the *C* corner and ground represents a shunt across the standard arm. The second requirement of the power supply is that the guard to ground insulation resistance be at least 10,000 megohms.

A simple power supply meeting the foregoing requirements could consist of a battery resting on a metal plate which is insulated from ground by supports of a high-insulation-resistance material. The metal plate, being the guard, would be connected to the *C* corner of the bridge. It is also necessary that the battery leads to the bridge be air insulated, as a first choice. As an alternate, the leads may be contained in an insulated metallic braid sheath with the sheath connected to guard. The outer insulation for the sheath should be of a material such as polyethylene to maintain the high guard to ground insulation. With such a power supply, there is no possibility of a leakage current path directly from the *A* corner battery lead to ground. Insulation resistance between the *A* corner, battery lead and guard is, as mentioned previously, a shunt across the battery, and therefore need not meet rigid requirements.

For convenience in operation, a guarded-battery power supply should consist of multiple batteries and a switch for selecting the desired bridge potential. The voltage selector switch should be mounted on the guard plate or separately guarded.

A-C Operated Guarded D-C Bridge Supply

To eliminate the need for battery replacement or recharging, a guarded power supply operating from a 120-volt 60-cycle line would be more desirable for use with the precision, guarded Wheatstone bridge. The circuit is shown in the upper section of Fig. 2. To minimize the effects of line voltage variations, a voltage regulating transformer is used to supply the power to an adjustable autotransformer. The output of the autotransformer feeds the primary of the first isolation transformer which has its core and electrostatic shield connected to ground. The secondary of the first isolation transformer is connected to guard through the center-tapped primary of the second isolation transformer. Thus, these direct-connected transformer windings are the guard for the rectified output of the second isolation transformer.

The guard-to-ground insulation resistance is largely determined by the quality of the first isolation transformer since the insulation resistance of the secondary winding of this transformer is the controlling factor. Transformers meeting *MIL-T-27* specifications are required to have a minimum winding-insulation resistance of 10,000 megohms. Actual measurements on the isolation transformers used in this power supply showed insulation resistance in excess of 100,000 megohms at 90% relative humidity.

The rectifier and filter section are insulated from the guard circuit by the second isolation transformer. This transformer, the rectifier, and the filter components are physically mounted on an insulated metal guard plate. The voltmeter is mounted on the front panel but

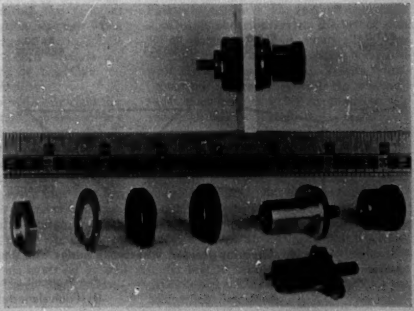


Fig. 3. Guarded binding post assembly

is separately guarded and insulated from the panel.

Although not shown in Fig. 2, a range-change switch is also incorporated in the guarded power supply with the switch guarded and insulated from the front panel. This switch changes the voltmeter range and voltage taps on the secondary of the second isolating transformer.

An *L-C* filter is used to provide a low internal impedance and therefore better regulation for various bridge settings. The output voltage is adjusted by setting the autotransformer, which has approximately full rotation for either output voltage range. These ranges are 0 to 10 and 0 to 100 volts d-c with up to 40 milliamperes output for any output voltage setting. The a-c component of the output voltage is less than 10 millivolts for any output current.

In operation, it has been found that the electrostatic shielding of the first isolation transformer is not perfect and results in the guard circuit having some a-c potential with respect to ground. This causes no trouble when using a galvanometer detector which is inherently a good 60-cycle mechanical filter. With a well-filtered electronic detector, there is no difficulty, but with an unfiltered electronic detector, a zero shift will be encountered. This undesirable effect can be eliminated by adding a filter network between the bridge and the unfiltered electronic detector.

Guarded Electronic D-C Null Detector

The desirability of measuring resistors accurately in the megohm range introduces the requirement of obtaining a detector with adequate sensitivity. This requirement has been met in the design of a stable, sensitive, low-noise detector with a filtered input and an acceptably high-input impedance. The detector is designed with a specially insulated floating-input circuit so that it may be used with one terminal grounded or both terminals ungrounded. The indicating element is a zero-center meter. The circuit is so designed that maximum sensitivity is obtained around the zero point and yet a nonlinear response characteristic allows extreme unbalance without off-scale deflections. The detector is also equipped with a sensitivity control switch and a zero adjust control. This latter control is necessary to adjust for the slight zero drift experienced during the initial warm-up period.

As presently designed, the detector has a 40,000-ohm input resistance and operates across approximately 100,000 ohms maximum in the bridge network. The sensitivity is sufficient under these conditions to show a 0.01% change in a 100-megohm resistor with 100 volts applied to the bridge. This condition represents approximately 0.3-microvolt change and corresponds to a 2-millimeter deflection. The maximum noise level and maximum zero drift after warm-up total less than one-half of this value.

A Method for Determining the Accuracy of High-Megohm Resistors Using Low-Resistance Standards

The requirement to construct d-c Wheatstone bridges to measure with high accuracies above the 1-megohm range has introduced the additional problem of checking these bridges for over-all performance under actual operating conditions. For values up to 1 megohm, the common practice has been to make absolute resistance measurements of the ratio and standard arms of the bridge and then to check these measurements by using the equipment to measure certified primary resistance standards. The ratio and standard arms of a Wheatstone bridge rarely exceed a value of 100,000 ohms and resistors up to these values can be checked to within 0.005% of their absolute value by comparison with certified standards. If a bridge is constructed to make measurements above the megohm range, the absolute value of the three arms of the bridge may be determined with a high degree of accuracy, but the final bridge check begins to lose its significance due to the lack of a high-accuracy certified primary standard.

A method may be used to simulate accurately primary standards above this range and provide a satisfactory over-all bridge check. The principle involved is that of the Y-delta transformation.[12] It is commonly known that impedances arranged in the form of a Y may be converted to another set of impedances in the form of a delta without affecting the values of the impedances between the three end points of the network.

Referring to Fig. 4, it can be seen that the Y circuit consisting of resistors R_{AO}, R_{CO}, and R_{DO} can be converted to the equivalent delta circuit R_{AC}, R_{AD}, and R_{CD} by means of the familiar transformations:

$$R_{AD}=R_{AO}+R_{DO}\quad\frac{R_{AO}\times R_{DO}}{R_{CO}}$$

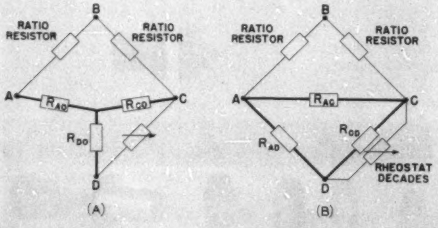
and

$$R_{AC}=R_{AO}+R_{CO}+\frac{R_{AO}\times R_{CO}}{R_{DO}}$$

and

$$R_{CD}=R_{CO}+R_{DO}+\frac{R_{CO}\times R_{DO}}{R_{AO}}$$

If R_{AO} and R_{DO} are each nominally 1-megohm resistors known to within 0.01% of their absolute value, and R_{CO} is a resistor whose value is determined from the table in Fig. 4 and is known to within 0.005% of its absolute value, then R_{AD} may be determined to a value within ±0.025%. The resulting value of R_{AC}



NOMINAL VALUE OF R_{AD}	R_{AO} (OHMS)	R_{CO} (OHMS)	R_{DO} (OHMS)	EQUIVALENT R_{AC} (OHMS)	EQUIVALENT R_{CD} (OHMS)
12 MEGOHMS	10^6	10^5	10^6	1.2×10^6	1.2×10^6
102 MEGOHMS	10^6	10^4	10^6	1.02×10^6	1.02×10^6
1002 MEGOHMS	10^6	10^3	10^6	1.002×10^6	1.002×10^6
10,002 MEGOHMS	10^6	10^2	10^6	1.0002×10^6	1.0002×10^6

Fig. 4. Checking guarded Wheatstone bridge with simulated standard megohm values using Y-delta transformation

A—Y circuit using certified standards
B—Equivalent delta circuit

Fig. 5. Precision, guarded resistance measuring facility

has no significant effect on the bridge balance. The value of R_{CD} does affect the bridge balance, but this effect may be precisely determined mathematically.

The simulated high megohm standards formed by this conversion permit the use of wire-wound resistance standards which have the advantages of high stability, low temperature coefficient, and low thermal properties. Precautions, however, must be observed in using these standards. The standards must be physically located in such a manner that the insulation resistance between the *A* and *D* points of the Y circuit shall be limited to an acceptable minimum. If the insulation resistance is low, the effect on the accuracy of the measurement will be the same as if this resistance were shunting the high megohm resistor formed by the Y-delta transformation. Proper use of a guarded terminal as shown in Fig. 3 at the *A* point of the Y network will minimize the errors due to this low insulation resistance.

This method of an over-all operational check on a Wheatstone bridge assembly provides an accurate means for checking the bridge assembly errors for the range of unknowns above 10 megohms. It also provides a practical method for checking bridge performance under ambient conditions of humidity.

Summary

The complete precision, guarded resistance, measuring facility as proposed is shown in Fig. 5. Each of the three components has been built; in fact, several of the precision, guarded bridges are in service. The complete guarding of the entire facility will insure a higher precision of measurement, lower maintenance, and provide a facility which can be used either in a modern standards laboratory or in non-air-conditioned production areas.

Discussion

H. T. Wilhelm (Bell Telephone Laboratories, Murray Hill, N.J.): This paper makes several contributions to the art of precise d-c resistance measurement, particularly in the field of measurements in the megohm range.

Since 1943, shielded d-c bridges have been used in the Bell System to measure with a precision of a few parts per million the d-c resistance ratio of two resistors in the megohm range. These bridges are described in the April 1947 *Bell Laboratories Record*, cited as reference 9 of the paper. The shielding shown as a dashed-line rectangle in Fig. 2 of the afore-mentioned article is actually electrostatic shielding connected to ground, which serves two purposes: (1) to eliminate interference from changes in body capacitance and body static charges in the operator of the bridge, and (2) to avoid shunting the resistors under test with insulation leakage when measuring direct resistance ratio. This second objective agrees with what is accomplished by guarding in the Guarded Resistance Measuring Facility.

In the absence of formal definitions for guarding and electrostatic shielding, my idea of the difference between these terms is that guarding is essentially a technique for eliminating direct conductance between two electrodes, whereas shielding is a technique for eliminating direct capacitance between two electrodes. If this distinction is correct, it appears that this bridge and the bridge described by Mr. Wyeth are both guarded and shielded. It would be helpful to have formal definitions covering guarding, electrostatic shielding, and electromagnetic shielding.

N. E. Bonn (James G. Biddle Company, Philadelphia, Pa.): The authors have made a valuable contribution to the art of precision electrical measurement. The very effective use of the guard system combined with the application of the Y-delta transformation makes it possible to evaluate resistors as high as 10,000 megohms with a very high order of accuracy.

At the James G. Biddle Company, where the measurement of high resistance is an important part of the business, we are naturally interested in the design of such guarded bridges. But because our working standards are often subjected to high voltage, sometimes as high as 10,000 volts, we prefer a bridge arrangement which permits the application of such voltage to the resistor under test to take care of possible voltage dependency. This cannot be done with the bridge here described.

Of particular interest is the method of checking the performance of the bridge for multimegohm measurement by using available standards of relatively low resistance. This interesting, and presumably new, method deserves a more detailed discussion. Also, the data given in the table of Fig. 4 appear inadequate. It would probably have been helpful to those who are not expert in this field if the paper gave the procedure to be followed by the user in applying the Y-delta transformation, perhaps something like this:

1. Measure the unknown resistance X with the bridge in the regular manner to obtain a tentative value for $X=R_{AD}$. Record the reading R of the rheostat arm.
2. Calculate the value of R_{CO} from the first transformation equation using the tentative value of R_{AD} and the actual (not nominal) values of the standards R_{AO} and R_{DO}.
3. Arrange the Y circuit as in Fig. 4 using the two standard resistors and an accurate resistance box set to the calculated value of R_{CO}. Balance by adjusting rheostat arm and call this reading R'.
4. Calculate the value of R_{CD} using the third transformation equation.

The value of X obtained in the first measurement is correct only if

$$R=\frac{R'\times R_{CD}}{R'+R_{CD}}$$

If R_{AO} and R_{DO} are exactly 1 megohm each, as was assumed in the table of Fig. 4, the first and third transformation equations are easily simplified to read:

$$R_{CO}=\frac{10^{12}}{R_{AD}-2\times10^6}$$

and

$$R_{CD}=2R_{CO}+10^6$$

In this form the equations are certainly more comprehensive than the table since they may be applied to any value of X greater than 2 megohms.

It is interesting to note that with two 1-megohm resistors proposed in the paper, this check cannot be performed if X is equal to or smaller than 2 megohms, because R_{CO} either becomes infinity or assumes a negative value which means that the Y arrangement cannot be set up. If, however, instead of 1 megohm, R_{AO} and R_{DO} are each 1/2 megohm, the foregoing expressions for R_{CO} and R_{CD} become

$$R_{CO}=\frac{25\times10^{10}}{R_{AD}-10^6}$$

and

$$R_{CD}=2R_{CO}+5\times10^5$$

and can be used for checking the performance of the bridge for all values of X greater than 1 megohm. A 1-megohm standard with a tap in the middle would meet all requirements and would certainly be less costly than two 1-megohm standards of equal quality.

Additional references[1-3] on the use of guarding in d-c Wheatstone bridge circuits may be of interest.

F. H. Wyeth, J. B. Higley, and **W. H. Shirk, Jr.:** We are grateful to H. T. Wilhelm for bringing out in his discussion the lack of formal definitions for "guarding" and "shielding." We are suggesting to the AIEE Committee on Terminology that consideration be given to including these terms in the ASA-AIEE definitions.

The Guarded Resistance Measuring Facility on view during the meeting had been subjected to 86% relative humidity and 85 degrees Fahrenheit for over 24 hours in an all-weather test chamber. The externally located certified standards were connected to the equipment with shielded leads. The equipment was operated under the high-humidity condition through ports in the chamber. The results confirmed the theory and practical effectiveness of the guarding.

We also appreciate the comments of Mr. Bonn. The resistance measuring facility described in this paper is designed for measurements of resistors at potentials up to 100 volts, which is the maximum permitted under military specifications such as *MIL-R-93A*, *R-10509-B*, and *R-14293A*. Lower potentials are permissible, providing the detector has adequate sensitivity. We recognize that there may be a few special applications where higher voltages on the unknown resistors would be required and Mr. Bonn has mentioned one such application. In a precision Wheatstone bridge, however, it is not economically practical to make provisions for such high testing potentials as required by Mr. Bonn.

The comments by Mr. Bonn in connection with the Y-delta transformation are mathematically correct and illustrate a procedure for checking the bridge at any value of unknown resistance above 1 megohm. The suggested procedure, however, requires the use of an adjustable resistance standard. We wish to point out that to maintain a ±0.025% limit of error as stated in the paper, this adjustable standard must be known to 0.005% and introduce no leakage paths. These are difficult requirements to meet. It is our belief that fixed check points using combinations of fixed standards as given in the table of Fig. 4 are satisfactory. Other combinations may, of course, be used. It should be remembered that the individual bridge resistors and ratios can be checked for accuracy. The simulated high megohm standards are, therefore, used as an over-all check, including the effectiveness of the guarding and insulation.

A-C Controlled Magnetic Amplifiers

E. W. LEHTONEN
ASSOCIATE MEMBER AIEE

E. A. CRONAUER
ASSOCIATE MEMBER AIEE

PAST PRACTICE in a-c controlled magnetic amplifiers has required a relatively large resistance in series with the control windings to limit the circulating currents caused by the induced emf (electromotive forces) of the control windings. This resistor necessarily wastes signal power, and the realizable gain is much less than could be obtained from a d-c controlled amplifier.

To achieve higher gain with a-c control, an alternate method has been to demodulate the signal before using it to control the amplifier. This has several disadvantages, including drift, loss of signal power, and extra components.

This paper describes a method for controlling full-wave amplifiers with a-c signals which offers the following characteristics: no current-limiting resistors, no demodulator, response similar to d-c control amplifiers, and high gain. These characteristics are realized by arranging the control circuit so that the induced emf in the control circuit are substantially cancelled.

Among the other advantages of this type of amplifier are: the power efficiency of conventional full-wave amplifiers can be realized; and the high power gain makes it possible to control a relatively powerful magnetic amplifier with a low-power class *A* transistor, permitting the advantages of transistors and magnetic amplifiers to be combined.

Paper 58-773, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 11, 1958; made available for printing April 1, 1958.

E. W. LEHTONEN and E. A. CRONAUER are with the Sperry Gyroscope Company, New Hyde Park, N. Y.

The authors acknowledge the assistance of L. Demuth in the measurements included in this paper.

Steady-State Description

Assume the full-wave amplifier circuit of Fig. 1, and assume further that by unspecified means the firing angle α is set somewhere between zero and π. The cores are assumed to have the hysteresis loops shown in Fig. 2 with the flux level indicated at the instant the sinusoidal excitation voltage is going through zero to positive values. If voltage drops caused by the current i indicated in Fig. 1 are temporarily ignored during the half-line cycle when $0<\omega t<\pi$, e_{ca}, e_{R_1}, e_{R_2}, and e_t will have the values shown.

To find the voltage across N_c of core B,

$$e_{cb}=-e_{ca}-e_{R_1}+e_{R_2}+e_t \tag{1}$$

The voltage across R_2 is zero since CR_2 is blocking.

$$e_{ca}=\frac{N_c}{N_p}E\sin\omega t\Big]_0^{\alpha}$$

$$e_{R_1}=\frac{R_1}{R_1+R_L}E\sin\omega t\Big]_{\alpha}^{\pi}$$

Substituting these values for e_{ca}, e_{R_1}, and e_{R_2} yields

$$e_{cb}=-\frac{N_c}{N_p}E\sin\omega t\Big]_0^{\alpha}-\frac{R_1}{R_1+R_L}E\sin\omega t\Big]_{\alpha}^{\pi}+0+E_t\sin\omega t \tag{2}$$

By adjusting the turns ratio of the transformer so that

$$E_t\sin\omega t=2\frac{N_c}{N_p}E\sin\omega t \tag{3}$$

choosing R_1 so that

$$\frac{R_1}{R_1+R_L}E\sin\omega t\Big]_{\alpha}^{\pi}=2\frac{N_c}{N}E\sin\omega t\Big]_{\alpha}^{\pi} \tag{4}$$

and substituting in equation 2 yields

$$e_{cb}=-\frac{N_c}{N_p}E\sin\omega t\Big]_0^{\alpha}-2\frac{N_c}{N_p}E\sin\omega t\Big]_{\alpha}^{\pi}+0+2\frac{N_c}{N_p}E\sin\omega t \tag{5}$$

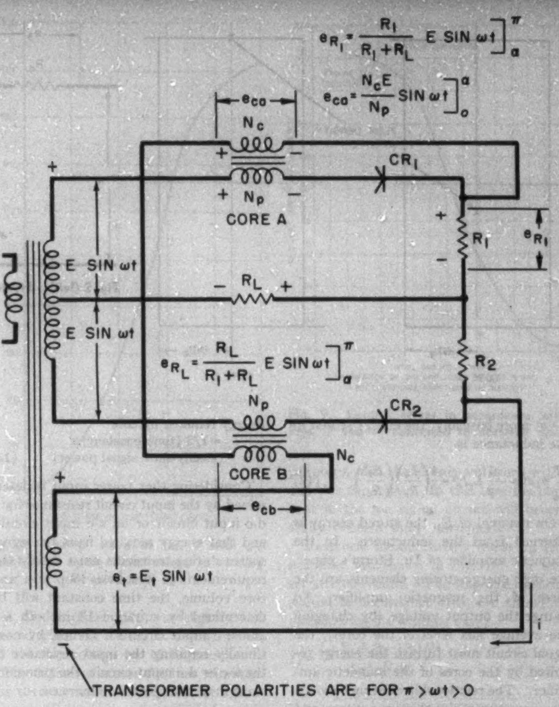
$$e_{cb}=\frac{N_c}{N_p}E\sin\omega t\Big]_0^{\alpha}+0\Big]_{\alpha}^{\pi} \tag{6}$$

Hence, core B will be resetting at the same rate that core A is setting. To meet the requirements of the **B-H** characteristic, winding C must have a current

$$i=+\frac{(NI)_E}{N_c}\Big]_0^{\alpha} \tag{7}$$

Therefore the average value of i over 1/2 cycle is equal to

$$\frac{(NI)_E}{N_c}\frac{\alpha}{\pi}$$



$e_{R_1}=\frac{R_1}{R_1+R_L}$ E SIN ωt $\Big]_{\alpha}^{\pi}$

Fig. 1. Full-wave amplifier circuit

During the half-line cycle where $\pi<\omega t<2\pi$, a similar process takes place but the current is reversed:

$$i=-\frac{(NI)_E}{N_c}\Big]_{\pi}^{\pi+\alpha} \tag{8}$$

The fundamental frequency of i is $\omega/2\pi$. This derivation shows that the rectified average value of i is related to the average value of e_{R_L} by the relationship

$$\frac{\text{average value of } e_{R_L}}{\text{rectified average value of } i}=\frac{\frac{1}{\pi}\int_{\alpha}^{\pi}\frac{R_L}{R_1+R_L}E\sin\omega t\,dt}{\frac{(NI)_E}{N_c}\frac{\alpha}{\pi}} \tag{9}$$

Taking into account the iR drop caused by this exciting current will not invalidate the analysis if an excitation frequency emf is introduced in series with e_t to furnish an emf equal to the iR drop. The value of this emf determines the output of the amplifier. This affords a means of controlling the output with an excitation frequency signal. Fig. 3 shows a circuit with an a-c signal voltage and a method of biasing added.

Time Constant

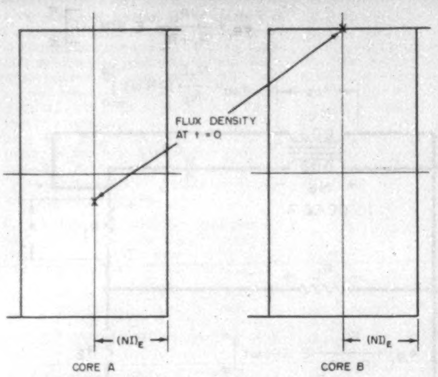
Dr. Storm[1] presents an equivalent analysis of a low-control Z, d-c input magnetic amplifier using square loop core materials. His conclusions are similar to equation 9.

In the d-c amplifier, the control circuit is effectively an R/L (reactance-inductance) circuit, as shown in Fig. 4. Assuming a step input voltage to this circuit, circuit analysis shows that the volt-time integral of the inductance is

$$\int e_c dt=-E_c\frac{L_c}{R_c} \tag{10}$$

The steady-state current through L_c is

$$I_c=\frac{E_c}{R_c} \tag{11}$$



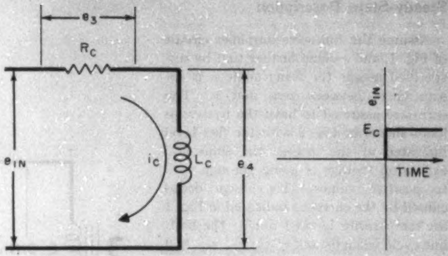


Fig. 2 (left). Hysteresis loops in units of flux density and ampere-turns

Fig. 4 (above). R/L circuit

Or, more basically, the energy stored in the inductance is

$$\int_0 p_L dt = -\frac{1}{2} L_c I_c^2 = \frac{1}{2}\left(\frac{L_c}{R_c}\right)\left(\frac{E_c^2}{R_c}\right) \qquad (12)$$

On removal of E_c, the stored energy is returned from the inductance. In the magnetic amplifier of Dr. Storm's paper, the only energy-storing elements are the cores of the magnetic amplifier. To change the output voltage (by changing the average flux level of the cores), the signal circuit must furnish the energy required by the cores of the magnetic amplifier. The relationship existing between the core energy signal source power and time constant, as stated in equation 12, may be restated as in equation 13.

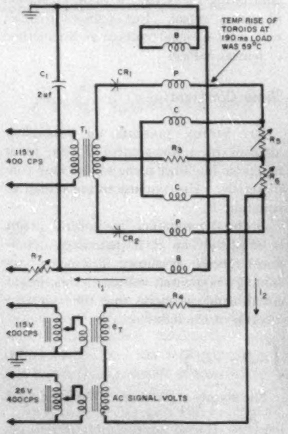

Fig. 3. Amplifier used to obtain data

Energy required by core
$$=1/2 \text{ (time constant)} \times \text{(steady-state signal power)} \qquad (13)$$

Considering that power input is determined by the input circuit resistance for a d-c input circuit or an a-c input circuit, and that energy required from the signal source during transients must satisfy the requirements of hysteresis loop area and core volume, the time constant will be determined by equation 13 in both a-c and d-c input circuits. Hence, by continually reducing the input resistance of the a-c or d-c input circuit, the time constant may be expected to increase.

Combination A-C and D-C Input Circuits

In a magnetic amplifier incorporating both a-c and d-c input circuits (neglecting control circuit iR drops), no coupling will exist in steady-state operation. Hence both types of signal circuits can be placed on the same amplifier without interaction. Then, by superposition, the firing angle (and therefore the output voltage) will be related to the signal currents by the following equation; see Fig. 3:

$$N_B \text{ (average value of } i_1 + N_C \text{ rectified average value of } i_2) = -(NI)_E \frac{\alpha}{\pi} \qquad (14)$$

where the core characteristics of Fig. 3 are described in Fig. 2.

When both a-c and d-c signal circuits are present, the time constant should be the sum of the separate time constants, just as if several d-c input circuits were used.

Measurements

An amplifier was assembled in accordance with Fig. 3. The toroid specifications were as follows:

Orthonik 0.001 tape
0.75 inside diameter by 1.125 outside diameter by 0.375 height
Winding P: 1,720 turns, no. *36* AWG (American Wire Gauge); resistance, 120 ohms
Winding B: 250 turns, no. *36* AWG
Winding C: 24 turns, no. *22* AWG

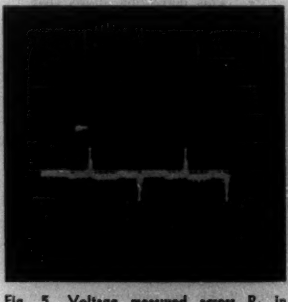

Fig. 5. Voltage measured across R$_4$ in Fig. 3 with no a-c signal voltage

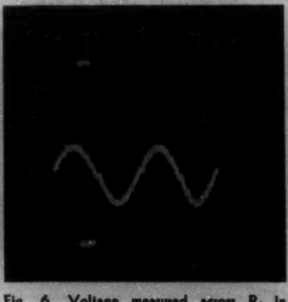

Fig. 6. Voltage measured across R$_4$ in Fig. 3 with 0.7-volt a-c signal

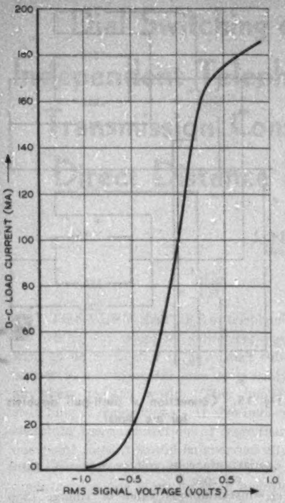

Fig. 7. Control curve of Fig. 3, current in winding B≅3.4 milliamperes

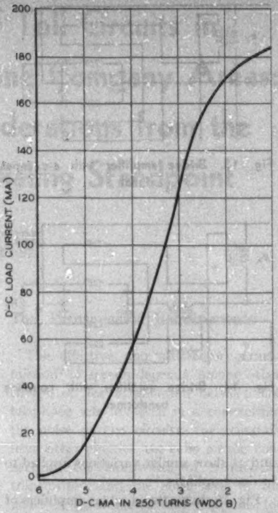

Fig. 8. Control curve of Fig. 3 with a-c signal circuit open, direct current in winding B varied with R_5

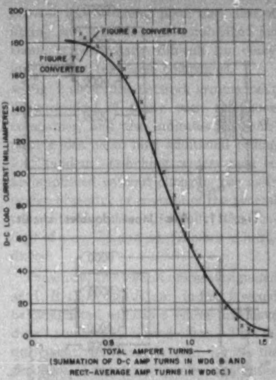

Fig. 9. Control curves in accordance with Figs. 7 and 8, converted to common units

CR_1, CR_2 = silicon diodes, 500-volt peak inverse voltage and 0.1-ampere forward current

R_5, R_6 = 20-ohm potentiometers set at approximately 15 ohms

R_3 = 400 ohms

R_4 = 1 ohm

T_1 = 400-cycle-per-second power transformer; 230-volt output center-tapped

R_7 = 50K potentiometer

C_1 = 2 μf (microfarads)

With the circuit adjusted in accordance with the steady-state description and with zero a-c signal voltage, the voltage waveform across R_4 was photographed, and is shown in Fig. 5. Increasing the a-c signal voltage to 0.7-volt rms produced the current waveform shown in Fig. 6. The gain of the oscilloscope was constant for both figures. The rms current in Fig. 6 is 20 ma (milliamperes). The a-c input circuit impedance is then 0.7 volt/20 ma = 35 ohms. This agrees roughly with a d-c resistance measurement of 31.5 ohms made on the a-c input circuit.

Figs. 7 and 8 describe the gain of the amplifier with a-c and d-c input signals respectively. One curve in Fig. 9 is a replot of Fig. 8 recording the signal in ampere turns. The other curve was found by summing the a-c and d-c signal ampere turns in accordance with equation 14. The correlation in Fig. 9 verifies equation 14. Empirically it was found that the amplifier gain was slightly improved when the a-c signal voltage phase led the line voltage by 15 degrees.

The capacitor across the bias windings was used to make the induced voltage of the resetting winding a section of a sinusoid. This is primarily for explanatory purposes, and the circuit will work without this capacitor. In this case the current in the a-c signal circuit will necessarily contain more harmonics.

Response measurements made on the amplifier are shown in Fig. 10. R_7 was set at 7,200 ohms. The response time expected in accordance with d-c theory is (considering d-c winding only)

$$T_c = \frac{I_L(R_L+R_p+R_s)N_b}{I_B R_B N_p 2f}$$

$$= \frac{0.1(535)250}{1.6 \text{ ma } (7{,}200)(1{,}720)(800)}$$

$$= 0.845 \text{ msec (millisecond)}$$

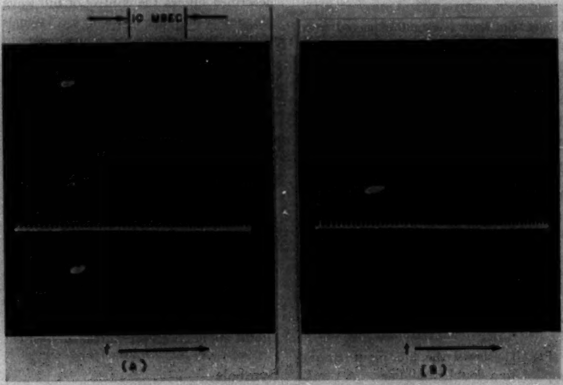

Fig. 10. Response of amplifier to an a-c step input voltage

A—Circuit in accordance with Fig. 3. Step input voltage = 0.3 volt. D-c load current change, 15 to 50 ma. Average Tc scaled from picture≅6.3 msec

B—Circuit in accordance with Fig. 3, except for the use of C_1 = 0.1 μf. Step input voltage = 0.2 volt. D-c load current change, 15 to 50 ma. Average Tc scaled from picture≅4.3 msec

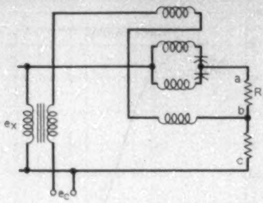

Fig. 11. A-c input doubler circuit

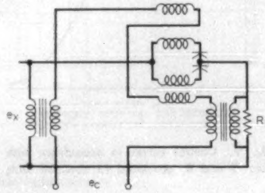

Fig. 12. A-c input doubler circuit with coupling transformer

The bias power needed to accomplish this is

$$I_B{}^2R_B=(1.6\times10^{-3})^2\,7{,}200 =18.4 \text{ milliwatts}$$

The a-c signal circuit power needed to accomplish the same change of output would be (see Fig. 8)

$$\frac{(\text{a-c signal voltage})^2}{\text{a-c signal circuit resistance}}=\frac{(0.5)^2}{33}=7.55 \text{ milliwatts}$$

Hence the time constant expected from the a-c input circuit would be

$$\frac{18.4}{7.55}(0.845 \text{ msec})=2.06 \text{ msec}$$

Therefore the combined time constant would be

$$2.06+0.845=2.905 \text{ msec}$$

The effects of the capacitor C_1 have been ignored; hence the calculated time constant is low.

The driving voltage is probably greater in Fig. 10(A) than in (B) because of nonlinearities in the control curves.

Other Variations of the Circuit

Fig. 11 shows the a-c input circuit applied to a doubler amplifier. A transformer could be used instead, as shown in Fig. 12. This variation permits reduced resistance in the signal circuit and the convenience of isolation between signal and excitation circuits. Figs. 13 and 14 show similar variations applied to bridge amplifiers.

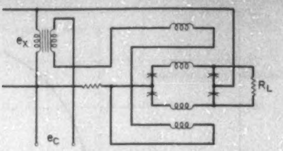

Fig. 13. Bridge amplifier with a-c input signal

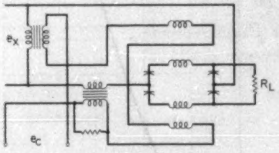

Fig. 14. Bridge amplifier with coupling transformer

Fig. 15 shows two doubler amplifiers of the type shown in Fig. 10, connected to form a push-pull amplifier. It will be noticed that the transformers used to introduce the excitation frequency voltage are bucking and are therefore superfluous. Many other circuit configurations are possible, but need not be mentioned here.

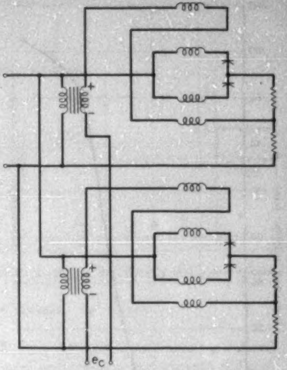

Fig. 15. Connection of push-pull doublers for a-c signal

Conclusions

The magnetic amplifier input circuit described allows the control of full-wave magnetic amplifiers with a-c signals so that the performance is analogous to d-c input amplifiers. Hence the power efficiency of full-wave amplifiers is realized. Also the power gains achievable are much higher than for intrinsically 1-cycle response amplifiers.

This input circuit permits the control of higher-powered magnetic amplifiers with low-power, class *A*, silicon transistors. This permits the advantages of each to be combined without the use of a demodulator. Summing of a-c and d-c signals is also possible.

It is applicable to many varieties of single-sided or push-pull amplifiers, as shown by the several examples of typical circuit applications presented.

Symbols

α = firing angle in radians

Dial Switching of Toll Circuits in Independent Telephone Company Areas: Transmission Considerations from the Direct Distance Dialing Standpoint

J. N. PETRIE
MEMBER AIEE

BY THE VERY NATURE of telephone traffic, any telephone subscriber may wish to be connected to any other subscriber in a continental area or possibly anywhere in the world. This implies switching of connections. It also implies switching these connections at more than one point since it would be economically impracticable to concentrate all switching operations at one point for even a single metropolitan area. With subscriber line switching on a decentralized basis, it naturally follows that switching centers themselves must be switched in order to accomplish economical interconnection of any two telephone subscribers.

Requirements for switching have been set up on the basis of a systematic plan which has been in effect for many years and is most commonly known in the commercial telephone communications industry as the "general toll-switching plan."[1] This paper will not go into the details of this plan except to point out that the present version of it presupposes assigning every telephone exchange into one of five classes. Fig. 1 shows the class designations and relationships as well as the different paths which might be involved when subscribers in two different offices communicate with each other. If these are class *5*, a total of eight switches or nine circuits (not counting the subscriber lines) may be involved. The operation of telephone connections involving several switches presents some challenging problems. This paper will be confined to only one of these problems, that of meeting the transmission requirements.

The Transmission Requirements

The effective and satisfactory transmission[2] of speech depends, among other things, on the attenuation between the telephone sets involved in a connection, the noise on the circuits, the crosstalk from other circuits, the echo on the connection, the bandwidth of frequencies transmitted, and the noise level at the point of transmission and reception (or more precisely, the acoustic conditions surrounding the speaker and the listener). In modern long-distance telephone circuits, the major factors contributing to the quality of a connection from a transmission point of view are attenuation and echo. These factors are to a large extent dependent on the "return loss" obtainable at 2-wire switching points. Return loss is primarily a measure of the degree of balance existing at the hybrid coils (which are invariably involved in these connections), and is therefore an indication of the magnitude of the echo which may be expected. On connections having low attenuation the echo tends to be even more noticeable. The problem of complying with transmission requirements of the general toll-switching plan, and also of fitting into classifications established for them, is particularly difficult for many independent telephone companies.

Fig. 2 shows the network arrangement quite typical of many such telephone companies, and also indicates this company's idea as to how additional coding for "tandem" switching centers may be accomplished without changing the basic design objective or concept of the general toll-switching plan. Basically, the concept of a no. *5A* and no. *5B* office is introduced.

Presently, the several offices designated as *A*, *B*, *C*, *D*, and *E*, etc., in Fig. 2 would be designated as class 5 offices and have direct trunks to a class *4* office. This requirement, however, is contrary to the practices of many companies who desire to operate what might be termed "county-wide" networks and, for economic reasons, would not wish to provide direct circuits from the several offices such as *A*, *B*, *C*, *D*, and *E* to the class *4* office. Alternatively, all offices classed above *A*, *B*, *C*, *D*, etc., (end offices) would necessarily have to be upgraded from a class *5* to a class *4*, a class *4* to a class *3*, etc., in accordance with the current general toll-switching plan. This would be a distinct hardship, especially on the Bell System.

To switch circuits at a tandem office, designated as the no. *5-A* office, presents a number of important and difficult transmission problems when working into the nation-wide DDD (direct distance dialing) network. Also some engineers believe that service rendered through a PBX (private branch exchange) is fundamentally similar to that rendered through "tandem" switching offices. Certainly PBX's constitute a special transmission problem unless they are to have long distance trunks direct to toll centers

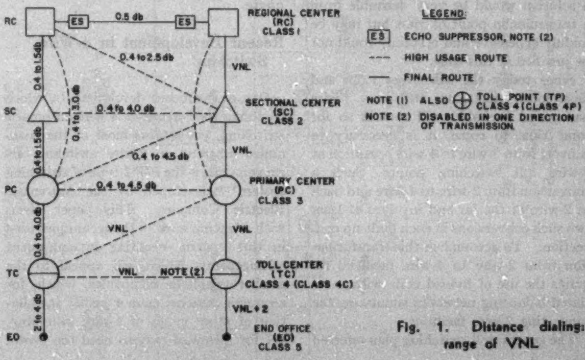

Fig. 1. Distance dialing: range of VNL

Paper 58-386, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted October 4, 1957; made available for printing April 30, 1958.

J. N. PETRIE is with the Automatic Electric Company, Northlake, Ill.

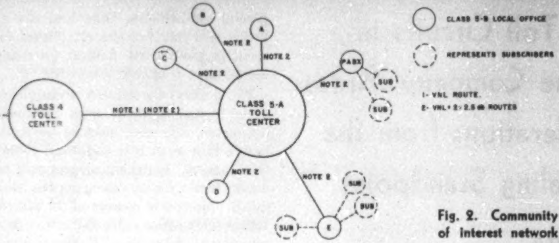

Fig. 2. Community of interest network

rather than to their own end offices. From a transmission standpoint, PBX does constitute the same problem as the outlying offices previously designated by the letters, *A*, *B*, *C*, and *D*, and is therefore in the same category.

The Nature of Telephone Circuits

Telephone conversations are bidirectional or duplex in nature, i.e., conversation must be possible in either direction over a single connection and reversible at will without any delay or noticeable interference to the talkers. To meet this requirement, it would be highly desirable to have available separate 1-way circuits for each direction of transmission, each equipped with a transmitter at one end and a receiver at the other, thus providing for 2-way conversation at all times, and at a loudness level limited only by the amount of amplification introduced in the respective 1-way transmission paths. Carrier channels, which are used extensively for long-distant telephone purposes, do provide bidirectional full duplex (or what are more commonly known as 4-wire) circuits. By the provision of suitable 4-wire local trunks and subscriber loops the objective could be achieved of an over-all 4-wire transmission path. Such a solution would be very desirable from a transmission point of view but may be unduly expensive and certainly could not be justified at this time.

Since today the subscriber loop, and most local trunks, are still on a 2-wire basis, and probably will remain so for some time to come, it is necessary to convert from 2-wire to 4-wire operation at 2-wire toll switching points. Such a conversion from 2-wire to 4-wire and back to 2-wire at the far end involves at least two such conversions in each built-up connection. To accomplish this transformation from 2-wire to 4-wire facilities requires the use of hybrid coils with associated balancing networks simulating the connecting 2-wire facilities.

The general toll-switching plan referred to in the foregoing is based on extensive use of 4-wire long-distance circuits, and 4-wire switching whenever economically feasible. No doubt, ultimately, all of the long-distance circuits and trunk circuits will be carrier derived and 4-wire switching will become more popular, so that the desirable characteristics of 4-wire operation can be achieved. Actually, 2-wire switching offices will be in use for years to come; however, it would still be desirable to take advantage of the favorable characteristics of 4-wire toll-switching while retaining the 2-wire local circuitry and equipment.

Requirements for 2-Wire Switching

Experience indicates that when a 27-db (decibel) return loss between circuits is attained at a 2-wire switching office, for all intents and purposes the performance will be comparable to that of a 4-wire switching arrangement. However, this involves a considerable initial expenditure and continuing effort and expense to maintain the degree of precision and control over the plant facilities found necessary to retain the 27-db return loss objective. At points where the 4-wire facilities are actually switched to 2-wire end links, a 15-db return loss will usually be adequate.

Recent Development in 4-Wire Switching

One of the recent developments, which combines the features of 4-wire automatic switching, yet retains most of the economies inherent in 2-wire switching arrangements, is the *FW-1* type of switching system[3–6] developed by the Automatic Electric Company. This paper deals with adapting some of the techniques used in this system, resulting in equipment arrangements which will appeal to the smaller telephone companies, which, for economic reasons, cannot justify installation of other types of 4-wire switching, yet for technical reasons need the 4-wire performance inherent in this switching arrangement. Such a solution involves using 4-wire toll-switching techniques not dependent on return losses at any class of office and not requiring a manual toll switchboard. To appreciate the significance of this arrangement it is necessary to review several possible conditions.

Fig. 3(A) shows diagrammatically what the problem is in terms of present typical plant facilities, attenuation, and return loss considerations. The return loss at the no. *4* office will be of the order only of 15 db. It should be noted that calls from a no. *4* office to the no. *5B* office (condition *A*) do not meet DDD minimum transmission requirements of 4 db as presently established, since no gain can be switched in at no. *5A* office.

Fig. (3B) shows a somewhat similar arrangement ultilizing 4-wire switching at a no. *4* office which results in an improved return loss figure; however, again no provision is available for gain switching at the no. *5A* office; therefore the transmission loss from no. *4* to no. *5B* end office (illustrated by condition *A*) exceeds the 4-db objective. Condition *B* shows that better than the minimum transmission requirements are attained when the call terminates at the no. *5A* office.

Fig. 4(A) indicates what might be expected if 4-wire switching were provided at tandem switching centers (designated as the no. *5A* office) with carrier-derived channels connecting it to the no. *4* office. In this instance, 2-wire switching is assumed to be used at the no. *4* office, resulting in a return loss of 15 db. It is particularly significant to note in condition *A* that high return loss and, consequently, gain switching is possible at the no. *5A* office. This will permit VNL (via net loss) switching between the no. *4* and no. *5A* offices and effectively make a no. *4* office out of the no. *5A* office, permitting better than minimum standard transmission to no. *5B* end offices. Condition *B* shows the transmission arrangement on traffic-terminating in the no. *5A* office. The 10-db return loss indicated is predicated on the improvement obtained by insertion of the 2.5-db pads in both the line and network branches of the hybrid coil. This improvement is essentially a "by-product" derived from the "padding out" of the carrier channel from the VNL condition to the TNL (terminal net loss) condition. No change in loop gain on the carrier channel itself is involved. It should be noted that the transmission losses from the no. *4* to the no. *5A* or no. *5B* offices are substantially identical and within the transmission objectives for an end office.

Fig. 5. Pad-switching arrangements

The application of 4-wire switching to a class *4* office, as well as to the no. *5A* offices, as shown in Fig. 4(B), has the effect of improving the return loss substantially, and thus permits exceeding the minimum performance standard currently established for a 2-wire switched office, namely 27 db, without the need for expensive office balancing. The conditions at the no. *5A* office remain unchanged from those assumed in Fig. 4(A).

Fig. 5 indicates schematically how the net loss is controlled and network switching accomplished in the *FW-1* switching equipment. Condition *A* shows 4-wire switching of two carrier channels at a class *4* office and the pad values involved. The link from the class *3* office to the no. *4* office, as well as the link from no. *4* to the no. *5A* office, would be operated at VNL = 0.5 db. However, when switched together on a 4-wire basis, the over-all loss from the no. *3* to the no. *5A* office is also only VNL = 0.5 db. This is desirable and permissible because 4-wire switching is essentially transparent. Condition *B* shows 4-wire switching of a carrier channel and a physical trunk at a no. *5A* office. It is assumed that the physical circuit is set up for operation at 2.5 db and equipped with a precision network. Condition *C* shows the pad values and compromise network when terminating on a local subscriber loop, either at no. *4* or no. *5A* office.

Fig. 6 shows the basic philosophy behind the "tail-eating"[7] switching scheme used in the *FW-1* switching system and used as a basis for the solution outlined in this paper. Four-wire terminating sets of the "two-repeating-coil" version are shown as the transformer action involved is more easily understood. Actually, any hybrid coil arrangement or equivalent 4-branch network functions in the same manner. The heavy arrows indicate the instantaneous voltage involved in west-to-east transmission while the light arrows indicate east-to-west transmission. It will be apparent that voice voltages originating from the West input terminals cancel out in the West output and the East input terminals, while adding in phase only at the East output. Conversely, voice voltages originating from the East input terminals appear only at the West output terminals. The loss in either direction of transmission through such a connection depends only on the transformer losses and associated wiring and usually is less than 1/2 db.

Field of Application

From the foregoing, it is evident that a tail-eating 4-wire switching arrangement has considerable merit at class *5A* or higher class offices. In each instance it may be utilized for either terminating or through switching to achieve results as shown in Fig. 4(B). On this basis, the performance will be better than that which is anticipated for 2-wire switching at corresponding offices as presently visualized for the general toll-switching plan. When used at the no. *5A* offices, the switched trunk return loss will be better than 20 db, whereas only a 15-db return loss is expected to be accomplished with the 2-wire class *4* office switching arrangements. At the no. *4* offices the return losses would be of the order of 30 db or better with the tail-eating arrangement.

Some features of the tail-eating hybrid coil connection are

1. Its performance is 4-wire equivalent transmission.
2. Initial and recurring expense (due to

Fig. 6. Instantaneous current relationships: tail-eating hybrid connections

subsequent changes or additions) of balancing an office to achieve or retain a high return loss is not necessary.

3. It is flexible in open application.

4. It permits interconnecting terminal repeatered physical circuits or carrier channels of all makes.

5. It interconnects a variety of impedances.

6. There is automatic insertion of up to 6 db of gain.

7. It is relatively inexpensive when applied in new or existing offices not having toll transmission switches.

When network terminals are switched to precision networks which are designed for the matching of a specific facility and without specific office balancing, it is possible to achieve a distinctly higher return loss on 2-wire connections than would be possible if the switching were done on a compromise network basis.

Utilization of the tail-eating type of switching arrangement at tandem switching centers (no. *5A* office) may have far reaching implications in the application of Strowger automatic toll-ticketing equipment. It may also have a major effect on the number of toll-connecting trunks required. It should be noted that the successful application of 4-wire switching at a no. *5A* office presupposes utilization of toll grade regulated carrier channels interconnecting the no. *5A* office with the no. *4* toll center. Carrier telephone systems of this type already constitute a substantial portion of such applications.

Summary

The *FW-1* type of switching scheme provides features and transmission characteristics equivalent to those of a directional 4-wire switching system but at only a nominal increase in cost over present commonly used 2-wire toll-switching arrangements. The use of this scheme permits gain switching at tandem switching offices, and thus solves a difficult transmission problem for community-of-interest telephone systems when it is integrated with the nationwide DDD network. The conversion of most existing offices to this switching arrangement will generally involve replacement of existing intertoll switch trains and their associated wiring. In those situations where a new installation is contemplated the superior features of this arrangement certainly justify the slight additional cost.

Factors Affecting the Use of Over-the-Horizon Links in Telecommunication Networks

CHARLES A. PARRY
NONMEMBER AIEE

THE SCATTER propagation mechanism has placed a new tool in the hands of the communication engineer. Long spans with great reliability have become feasible, and a supporting technology of high-powered transmitters, huge antennas and multiple receivers is available. In order that scatter circuits be used to full advantage as integral parts of the communication structure, more than determination of acceptable performance standards is required. It is necessary to assess the extent to which these links can be incorporated in existing facilities, and can supplement existing techniques.

This examination requires both a philosophical and technical approach. Up to the present time little has appeared in the literature which considers both the capabilities and the optimum utilization of the scatter link as a communication tool. A considerable amount of detail has appeared dealing principally with specific behavior patterns or component development.[1,2] Some papers have generalized with respect to performance limitations,[3,4] but in general these need revision in view of more recent information and cannot be considered for serious design.

It is the purpose of this paper to discuss the factors which influence the use of multichannel scatter links, particularly in relation to national telecommunication network planning. Scatter is a specialized technique and each individual possibility has to be examined on its own merit. It should be borne in mind, that for this reason, this paper is offered only as a guide toward final evaluation.

Generalization

It is necessary at this point to discuss the use of generalizations as they apply in the present discussion. In order to evaluate the scatter circuit in terms that will permit its utility to be assessed relative to other communications facilities, it is necessary that certain generalizations be made. This technique is, of course, quite common in the art. However, scatter presents a particular problem on which there should be a note of caution. In those cases when it is possible to make use of the generalizations, it is also likely that other communication methods would be suitable. By its very nature, therefore, scatter lends itself to those areas which present special problems. It is of a particular nature rather than general. This implies that while the fundamentals of the scatter method must be known, each circuit requires treatment case by case, which negates against the use of generalizations. It should be understood therefore, that although it is necessary to use generalizations in order to discuss the subject intelligently, basic recommenda-

Paper 58-383, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted February 4, 1958; made available for printing March 17, 1958.

CHARLES A. PARRY is with Page Communications Engineers, Inc., Washington, D. C.

tions laid on such a framework may prove to be quite misleading. This point should be retained when evaluating the ensuing text. It is because of this difficulty in generalization that philosophical concepts related to implementation must be evolved, the better to establish the specific areas for which scatter may be suited. Furthermore this may indicate modus operandi which will open a greater market to the use of this technique.

Evaluation of Preferred Techniques

When a decision must be made as to the implementation of a given service—and the world is used here as a generic to cover a link, circuit, technique, or whatever may be involved—certain judgment factors must be established for guidance, otherwise the results must be completely arbitrary. Admittedly the arbitrary judgment of an experienced engineer, may yield what ultimately proves to be correct results. The difficulty with this process is that no behavior pattern is established, and subsequent decisions cannot be made with equal certainty of success.

These judgments are an attempt to define the acceptable limits for the important criteria of the service, so that the final decision ascribes proper "weighting" to all relevant facts. It should be realized, however, that many of the details which must be considered reduce to subjective evaluation.

For instance, if a given administration considers that it is too difficult to train staff to operate a given service, who can prove this incorrect? And how can the importance be assessed other than by the ultimate opinion of individuals. If it can be shown that the service increases revenue so that a school can be established for training, how can this new fact be weighted other than by human judgment? There are many facets of a communication network which must be considered in the same way. The net results are the best attempts to correlate quantitative data with these subjective factors.

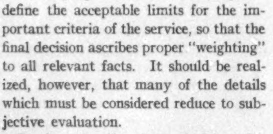

Fig. 1. Units required in subscriber-to-subscriber link. Indicates the relatively small part played by radio link in large network

The principal parameters on which judgment should be made in the evaluation of a communication service are as follows:

1. Compatibility
2. Performance
3. Price of design error
4. Strategic implication
5. Operation and maintenance
6. Economic assessment
7. Administration

Applicable factors are discussed separately in this text, together with certain detailed aspects of the decision problem which appear to be related particularly to the scatter circuit.

Compatibility

It is always difficult for the engineer who has been deeply immersed in a development of great promise, to find there is a lack of immediate universal acceptance, and that the industry is not "revolutionized." For an understanding of this it is necessary to realize the way in which an art develops.

When a new technical field is opened, there is usually a spectacular rate of progress as new ideas become practical and are adopted. As the art develops, so too does the net invested capital. Trends which would obsolete this capital must offer something in return and mere "better performance" rarely has significance. Thus it becomes more and more difficult for an established industry to be revolutionized. Conservatism is proportional to invested capital and is the balance wheel for the overindulgent claims of new ideas. An established field automatically imposes restrictive limits on new developments if they are to be integrated with the existing services; and no development has any value unless it can be utilized. Thus there is a golden rule which states, "The utility of any service can only be measured in relation to what already exists." In order to be acceptable there must be a minimum conformity with these restrictions. This is referred to under the general heading of "compatibility." The radio industry has recently had this problem brought sharply into focus by the requirements of "compatible" color television.

It is important to emphasize, however, as was apparent in this latter instance, that intrinsic cost and performance capability alone are not sufficient criteria for the determination of compatibility. Also there are sometimes factors involved which lie deep in human psychology. It is the net assessment of both human and quantitative factors which ultimately determine the extent to which a new service is acceptable.

In general it can be stated that compatibility requires a study of a number of loosely related factors. These are as follows:

1. Economics
    a. Basic cost of implementation
    b. Cost of obsoleting other services
    c. Maintenance and other service costs
    d. Revenue
2. Integration with existing facilities
    a. Performance limits
    b. Additional equipment needed to interconnect to existing circuits
    c. Increased maintenance problems
    d. Logistics
    e. Extension of present services
3. Social technology
    a. Ability physically to implement new service
    b. Ability to stand capital investment with possible long-term amortization
    c. Staff training
    d. Schooling for public acceptance and use
    e. Administration of new service

The scatter circuit is only a small part of the complete communication link. An attempt to indicate this is shown by the typical subscriber to subscriber circuit of Fig. 1. This has the advantage that new problems have proportionately less impact on the total task; the disadvantage is that specialized conditions may be demanded by a disproportionate part of the entire system. Furthermore, scatter is only one of several available operational techniques.

From these facts it may be deduced that the conditions requisite of compatibility for the scatter link will be quite extensive, embracing many fields of endeavor. A detailed study patterned on the basis of the factors outlined in the foregoing list is usually essential.

Performance

It is not the purpose of this paper to analyze the details associated with the evaluation of performance characteristics. Nevertheless it is essential to outline these broadly in order to assess the capability of the scatter technique relative to other methods. Furthermore, new commercial opportunities may become apparent in this process.

For the following discussions, median path loss had been obtained from the latest data made available by Norton,

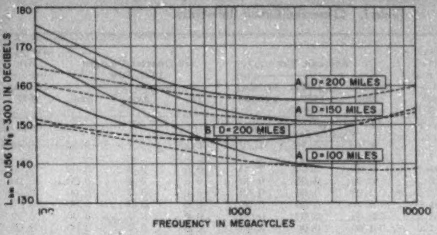

Fig. 2. Relationship between frequency and transmission loss

g	18	dual	95–90
h	28	quadruple	99–99
i	28	dual	95–90
j	60	dual	99–99
k	60	quadruple	99–99

Data apply to single-link system

based on his original paper.[5] Diversity improvement is based on ratio squared combiners as outlined by Altman and Sichak.[6] Long term fading is established by the most recent information evolved by Norton in an unpublished report. Medium aperture coupling loss is determined by Stara's method.[7] A total line loss of 2.5 db (decibels) at each end of the system has been allowed in all cases.

FREQUENCY OF OPERATION

Up to the present time, the variety of frequencies used has arisen, not so much from a study of operation parameters, as the necessity to make use of equipment already in production. As more knowledge becomes available this situation is likely to alter.

Early data seemed to indicate a relatively simple relationship between transmission loss and frequency.[3] More sophisticated analyses have shown that a complex relation exists. Fig. 2 has been drawn on the basis of present information to show this dependence, and certain conclusions can be drawn from this data. In so far as transmission loss can be used as a guide, the "general" optimum frequency centers around 2,000 mc/sec (megacycles per second). There is little difference to be seen over the range 1–4,000 mc/sec for a wide range of conditions. For short paths, higher frequencies tend to become more useful, while for long paths, particularly those with high sites, low frequencies may be preferable.

However, the choice of frequency will be influenced by factors other than transmission loss. Not the least of these is the ease with which allocations in the required range can be obtained from controlling authorities such as Federal Communications Commission, or International Telecommunications Union. The lower frequencies, below say 1,000 mc/sec are likely to suffer in this respect.

At lower frequencies, the antenna structure required to give gain equal to that of large parabolas, can be much simpler and there can be a substantial reduction of cost. Since the lower frequencies tend to be favored by long spans, this question of cost may offset the problem of frequency allocation.

Perhaps even more significant is the pattern of interference which exists around the scatter installation. This has been under study by responsible organizations for some time. The growing use of scatter renders the problem more and more acute. Yeh[8] has established a method for calculating the interference field based on some of the methods evolved from these study groups. The high power usually involved means also that harmonics and spurious signals, even though well down, may be radiated with high absolute power. Front to back antenna ratio assumes considerable significance: This factor tends to increase with frequency in practical installations and may become of considerable importance at low frequencies.

Tentative recommendations appear to be taking the trend that scatter and microwave links on the same system are mutually exclusive. Certainly, before scatter is used, the interference pattern for all radiated frequencies should be determined. This is one powerful reason which should favor higher frequency allocations; the total interference field can be substantially reduced. Certainly it would appear preferable to keep the scatter frequencies above the microwave frequencies (on a common system) if this is at all possible.

Summing up, the choice of frequency is influenced by:

1. Transmission loss
2. Interference field
3. Possibility of allocation of frequency
4. Relative cost
5. Availability of equipment

CIRCUIT RELIABILITY

The term circuit reliability[9] is used here to refer to the effects of propagation. In order to indicate a specified outage effect, the fading ranges associated with both long term and short term fading have been indicated separately. For instance a curve 90%–99%, means that the long term fading margin has been taken for the 90% abscissas, and the short term margin for the 99%. The long term fading is of course considered to be gaussian, while the short term is Rayleigh, with the diversity effect included. Curves are based on complete lack of correlation of the short term phenomena. The circuit reliability is based on the signal P_t which just reaches frequency modulation receiver threshold. This is obtained from the relation

$$P_t = FKTB\epsilon \tag{1}$$

where

K = Boetzman's constant
F = effective noise figure
T = absolute temperature
B = noise bandwidth
ϵ = frequency-modulation threshold factor

We can put $P_t = W_t(A)$ where W_t is the transmitted power, and A the total transmission loss factor. This includes medium aperture loss and fading margins. It then is convenient to express the performance in terms of B/W_t; this has been shown in Fig. 3. The data here are based on 2,000 mc, and a noise figure of 8 db. A suitable figure for ϵ can be obtained from Stumper[10] and Crosby;[11] both authors indicate 10 db is adequate although values different from this are used by some engineers. Ten db has been used in Fig. 3.

It is convenient to refer to B/W_t as the "performance index" of the system since it clearly relates to the essential definitive parameters of the link. If we accept as a guide the concept that $d\ (B/W_t)/d_\theta$ should be a small, it would appear from Fig. 3 that B/W_t should preferably be <1. However, it should be noted that for low values of power, quite important distances and reliability can be achieved and this must be kept in mind for commercial development of the scatter industry. It is also seen that extremely important reduction in the ordinate can be achieved by a reduction in the reliability demanded. So far no literature has given a guide toward acceptable values for outage time; even the CCIR (International Consultative Committee on Radio)[12] has so far avoided the problem.

The following limits are suggested on a tentative basis:

	Long Term	Short Term
High grade telegraphic circuits	99%	99%
Medium grade telegraphic circuits	99%	90%
Telegraphic circuits with error-correcting techniques	95%–90%	99%–90%

Separate study indicates that voice circuits are not so vulnerable to the outage effect as telegraphic circuits, although further investigation is certainly required.

For voice channels the following limits are suggested:

	Long Term	Short Term
High grade circuits (This corresponds to an outage of less than one hour in a year)	99%	99%
Commercial circuits	95%	99%
Limiting or military circuits	95%	90%

It should be recognized however in connection with the last limit, that military requirements often dictate that telegraph circuits be connected over the voice channel: in the absence of adequate error-correcting equipment the limits shown would be too low.

It is perhaps useful to note that the reliability which is reasonably feasible, is still in excess of values ordinarily associated with high-frequency circuits. This leads to the serious consideration that the lower grade scatter circuit may serve a useful commercial purpose in bridging the gap between the long span high-frequency technique and the short-span very-high-frequency and microwave technique. Certainly there are many areas where excessive limits of reliability are uncalled for, yet better reliability is required than is possible with high-frequency circuits, and longer spans than is possible with very-high-frequency circuits.

EQUIPMENT RELIABILITY

Equipment reliability in practical installations is quite high. There are two basic reasons for this.

1. There are fewer actual operating units, involved in the scatter link than the conventional microwave system. There does not appear to be significant loss in reliability as the power of a given type of unit is increased, so the over-all reliability of the scatter link improves.
2. Maintenance is generally more effective. The large θ installation is always attended, while it is almost mandatory to have unattended microwave stations. In the former case, when breakdowns occur they can be corrected quickly since the station is staffed. Problems associated with dust infiltrating and poor weather conditions are greatly minimized, since much potential trouble is eliminated due to the normal maintenance procedure of keeping the building in good order.

Power failures, which contribute significantly to total unreliability figures can usually be quickly overcome. As discussed later, the scatter system, particularly when part of a national network, is likely to have its stations near to metropolitan areas. This usually insures that a relatively reliable local supply is available.

The high order of reliability for the typical installation is shown by Table I. The propagation outages in this particular chart tend to be a little misleading, since

the circuit was designed with more than adequate margin in this respect. The data are presented primarily to show that the circuit reliability compares very favorably with other communications systems.

SIGNAL-TO-NOISE RATIO

The absolute signal-to-noise ratio will depend upon a number of factors, and the minimum requirements have not yet been generally agreed upon. Certain aspects of this problem have appeared in the literature and some suggestions have been made.[9] There is reason to believe that satisfactory performance for national toll circuits can be achieved with a signal/weighted noise ratio of 40 db exceeded for 99% of the busy hour. For non-integrated circuits, the operational value of 34 db for 95% of the busy hour has been suggested. Lowest practical commercial design would be about 30 db for 95% of the busiest hour and for reasonable military circuits, probably 15 db for 99% of the busy hour. The activity factor during the busy hour should be determined by the class of service rather than that obtained in large exchanges operating at maximum traffic capacity.

It can be readily shown that the signal to weighted thermal noise ratio on the top channel of a frequency-modulation system at threshold, is given by[9]

$$S/N : \frac{BK^{-1}}{2bL_f}\,\epsilon\delta(M^2) \tag{2}$$

where

B = noise bandwidth of receiver
b = channel spacing
ϵ = crest factor at threshold (taken as 10 db)
K = weighting factor (taken as 0·5 for 4 kc channels)
δ = improvement due to the use of pre-emphasis and de-emphasis (taken as 2 for the top channel)
M = modulation index
L_f = load capacity factor

This may be put in the form

$$S/N = \left(\frac{s}{p_m}\right)^2 \left(\frac{p_L}{p_m}\right) \underbrace{\left(\frac{f_m}{2b}\right)\frac{2K^{-1}\epsilon\delta}{L_f}}_{\text{factor } A} \tag{3}$$

The first two bracketed terms correspond to similar factors used by Medhurst[13] in his evaluation of the signal to nonlinear noise S/D associated with bandwidth reduction.

There is no simple solution to equation 3. However, a satisfactory solution can be made by assigning a definite value to S/D. This is then plotted in terms of (p/p_m) and $(s/p_m)^2(p_L/p_m)$. If S/N is specified, (p/p_m) can be found and the associated band-width and deviation determined.

Both f_m and L_f depend on the number of channels, so that these computations must be performed for each particular system. Values of f_m based on the use of CCIF (International Consultative Committee on Telephony)[14] frequency allocations for the higher capacities are given in Table II.

Medhurst's value of S/D is based on the use of white noise test signal. A correction must be made to this in order to obtain the expected signal/nonlinear noise ratio S/N_1, in the operative system.[9] This correction is associated with the statistics of the multichannel signal, and it can be shown that

$$\frac{(S/N_1)}{S/D)} = \frac{bn^{1-\alpha}}{X(1.5)(10^9)} \tag{4}$$

where n = number of channels and X and α are constants determined by the slope of the load capacity curve. A recent study (a paper in the course of preparation by the author) has been made of this, and values of L_f suitable for toll quality circuits are also given in Table II. For these values $x \simeq \alpha \simeq 0{\cdot}5$ and the correction obtained from equation 4 has also been added to the table. This is based on a traffic activity factor of 0.25.

With S/N known, an appropriate value of S/N_1, can be determined. With n known, S/N can be established and equation 3 then solved.

In order to arrive at working numbers it was considered that the nonlinear noise from this effect should be 10 db below thermal noise. A further allowance of 8

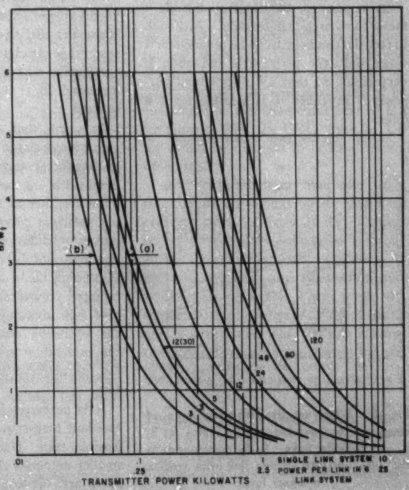

Fig. 4. Performance index versus transmitter power, with number of channels as parameter. All curves except a and b are based on 40-db signal to weighted thermal noise at threshold, with an activity factor $\tau = 0.25$. Bandwidth used includes 10% safety margin. Data based on B in Table II. These curves can be used in conjunction with Fig. 3 to establish reliability and θ values

A—30 db s/n
B—Low activity as in commercial system

db was made for the 6 links of a reference system. Hence for a signal-to-thermal-noise ratio of 40 db, $S/N_1 = 58$. S/D for the 120-channel system is then about 40 db.

Although some exception might be taken to these approximations, the bandwidth effect is such that even relatively large changes in S/N_1 will not call for any substantial change in B.

The end product of all the arithmetic associated with the determination of B is given in Table II. On the basis of this approach it can be expected that the nonlinear noise due to bandwidth restriction will be more than 10 db below threshold thermal noise for 99% of the busiest hour. This applies for at least 1–6 links.

The average value of B/d is 1.41, which suggests that the recommended ratio might well be 1.5 for all practical circuits.

Fig. 3 has been drawn with an ordinate B/W_t. Using equation 3 as outlined in the foregoing, B is determined for a given number of channels, so that the required power in terms of n and B/W_t, is easily established. This is shown in Fig. 4. Figs. 3 and 4 may now be used to obtain the transmitter power for a given reliability, distance, and number of channels for a 40 db signal-to-thermal-noise ratio at threshold. All the curves of Fig. 4 have been drawn to include a 10% increase in the bandwidth B indicated by Table II, as a safety margin.

The effect of reduced requirements is shown for 3 and 12 channels and is seen to reflect substantially on the required power.

As mentioned, these curves include a factor for 6 circuits in tandem. Although in fact the bandwidth can be reduced for a single link, the permissible reduction is very small, so that for all practical purposes B in Table II is suitable for 1–6 links.

Many commercial links require a relatively small number of channels. In the case of the scatter installation this requires a disproportionately high cost for the radio equipment. This is one of the factors which is adversely affecting commercial application. Part of the difficulty is associated with the fact that although channel capacity must be provided, the usage rate is relatively low. Concentrators have been described[15] which permit a much better matching of the capacity to the actual load although they do not appear to be yet available for radio circuits. In principle these use channels to provide searching functions, and then connect a multiplicity of lines to unused trunks. Thus if the expected activity is 0.1 the density could be increased by 2.5 times before reaching an activity of 0.25. This is the maximum value found in large exchanges[16] and therefore is not likely to be exceeded under conditions of full circuit utilization.

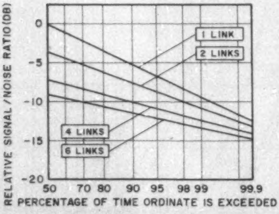

Fig. 5. Effect on signal-to-noise ratio of cumulative uncorrelated gaussian fading for 2, 4, and 6 similar links. 0 db corresponds to the ratio obtained in one link with median rf signal level

The application of this technique might well repay examination in the scatter field. Consider for instance a low density 24-channel system. A given reliability (constant B/W_t) could be achieved by a reduction of some 3 or more times the transmitter power, depending on actual values chosen. Alternatively, if the power is assumed to be fixed, a smaller antenna installation is possible. A figure of 5 channels has been chosen as representing a reasonable compromise between required performance and possible utilization of concentrators, in low capacity applications.

The same technique can be also applied to larger capacity systems of course. However, the need for larger capacity systems is associated with a greater social complexity and the utilization factor is increased so that concentrators cannot be used.

It is true that a reduction in activity factor is associated with a reduction in the loading factor, and therefore influences the bandwidth, as seen from equation 3. However, due to the problem of obtaining sufficient phase linearity in the frequency-modulation system, the bandwidth cannot be reduced beyond a certain point, i.e., a minimum bandwidth is required regardless of activity factor, so that full advantage cannot be taken of the operative condition. Consequently the preferable technique is to maintain the full activity by virtue of concentrators.

It is perhaps of interest to note that excellent long span circuits appear to be feasible with much lower power and smaller antennas than has been common in the art. It would appear that there is a definite place for the 100-watt installation, and this does not appear to be the minimum figure permissible.

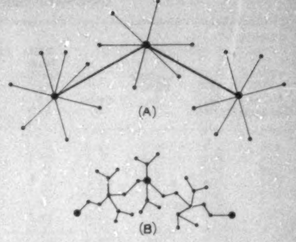

Fig. 6. Radial network required with scatter and the spine network possible with microwave, when both systems must serve intervening terrain

A—Scatter
B—Microwave

COMPANDORS

The prime advantage of the compandor of course is to raise signal-to-noise ratio and thereby permit what is basically, a lower quality circuit. An advantage of as much as 20 db can be obtained by this process.[17] However the compandor does not affect the circuit reliability, which is primarily a function of P_t/B. There is some reason to believe that slightly less outage time is permissible with the use of compandors, because loss of signal produces effects due to compandor action which tend to reduce intelligibility. However the system can be designed on a minimum bandwidth basis, i.e., $B = 4f_m$, since nonlinear noise-to-signal ratio is also improved.

Comparing this with B in Table I and with reference to equation 1, it is seen there is a reduction in the threshold. The extent of this reduction can therefore be used in conjunction with Fig. 3, to estimate the transmitter power for a given B/W_t. This technique makes the 5-channel system with line concentrators look particularly attractive. A 100-watt transmitter gives $B/W_t = 3$. The reduction due to minimal bandwidth is 4.5 db, making B/W_t now equal 1.06. An 18-foot dish with dual diversity and 95-99% reliability then gives an effective range of over 140 miles. This is a significant coverage with components which are within a reasonable price range. The cost of the radio equipment is now comparable with multiplex and such a system would appear to be economically attractive. Such a system will carry quite good standard voice-frequency telegraph circuits, since the circuit reliability is reasonable and the the channel S/N without compandors is adequate for this purpose.

The combined techniques of compandors and concentrators appears to be an approach worth a great deal more investigation by the industry.

FICTITIOUS CIRCUIT OF REFERENCE

Although the CCIR has not yet defined a fictitious circuit of reference for scatter systems there seems no fundamental reason why the concept could not be retained. Although it is very unlikely that a circuit of the reference length could ever exist with scatter, there is the real requirement that it may be part of such a circuit. From Fig. 3 it would appear that a reasonable distance for a link could be 250 miles. On this basis it might be suggested that the scatter reference circuit should consist of 6 homogeneous sections similar to the CCIR[18] suggestion for certain multichannel radio relays.

Since a typical microwave link is about 30 miles, the single scatter link in the reference circuit would be equivalent to eight microwave links.

The effect of fading over these links must be considered. Long term fading over a distance of 250 miles, may be considered as having a gaussian distribution with standard deviation of 4 db. Although some correlation may be expected over the several links, particularly from that component of the field associated with seasonal changes, it seems reasonable at this stage to establish parameters on the basis of uncorrelated fading. Curves for the combined distribution due to the several links based on Mack's[19] work are given in Fig. 5. Since the design figures used for the high quality circuits previously was based on 99% long term reliability, it would appear that the relative signal-to-noise ratio for a single section of the reference circuit should be about 4 db higher than for the overall system. Since higher reliability per section is also required, it can be expected that the power indicated in Fig. 3 should be increased by 4 db to make the data suitable for the single link of a fictitious reference system. Alternately this increase can be also obtained with the use of larger antennas than those indicated for the specific curves of Fig. 2.

ANTENNA LINES

A few words should be added concerning antenna lines. For the large θ installation, these lines may be quite long. With wideband systems the possibility of nonlinear noise due to echo can become quite serious since the noise power is proportional to the fourth power of line length.[20] A good match at the antenna can reduce this, but with high power links this may not be an insignificant factor.

Applicability

The scatter link has the basic advantage of being effective over relatively large spans without losing the principal advantages that have been normally associated with radio relays. In order to investigate the possibilities which scatter offers, it is necessary firstly to consider it on a functional basis. This will determine its appropriateness to specific communication requirements. The conditions which tend to favor scatter may be divided broadly into three categories.

1. Strategic: where the avoidance of the intervening stations represents a major step toward security.
2. Environmental: where the terrain prohibits the use of conventional radio relays, for instance,
   a. Desert
   b. Ocean
   c. Very rugged mountains
3. Commercial: where the economies permit scatter to be proved in
   a. Links providing special service for a particular organization, viz. mining, oil, and utility companies
   b. Links which are part of national or quasi-national networks

It is not useful to discuss the strategic application of scatter links. Strategic importance is rarely associated with economic factors, and may dictate developments which do not extend into the commercial field. This implies that growth of the scatter industry is likely to be overdependent on the state of world tension, budget allocations, and current military policies. Consideration along these lines is therefore not a part of this paper. It is also difficult to obtain a relative evaluation of scatter in those cases where a commercial radio relay is virtually excluded. Of necessity the economics of such a link have to be judged per se. Much the same remarks apply when the link provides a special commercial service.

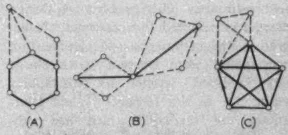

Fig. 7. Some methods by means of which alternative routing is possible for overflow traffic. Dotted lines are for high loss probability circuits

A—Ring system
B—Star system
C—General regional interconnection method

As part of a national or quasi-national network, however, the scatter link lends itself to particular functional arrangements. The purpose of a network is to service all significant areas of the community. Since scatter avoids contact with intervening terrain, areas between scatter stations must be served by a radial system. This is quite different from the spine structure possible with microwave, shown in Fig. 6. This has the advantage that the single scatter link carries the entire traffic between regions and it is possible that sufficient revenue can be obtained to amortize the investment.

Alternative routings for the overflow of traffic is an essential part of any network structure. Typical, though by no means exhaustive, methods are indicated in Fig. 7. It is difficult to see where the scatter link can fit into such a pattern. The long span implies either an equally long nonscatter overflow route, or that the scatter itself is for the overflow. In the first case it would appear that other linkage methods over the same route are feasible, and if economically suitable for overflow traffic, it is difficult indeed to see how a prime scatter link would be justified. In the second case it is doubtful if overflow revenue could justify its presence. This would seem to relegate scatter in the national network to acting as part of a backbone, without alternate routing facilities. This in turn would demand high reliability. If standby or power change over switching were to be considered as a fundamental part of the equipment, then the CCIT limit of 150 ms would be dictated in order to avoid drop outs.

Also it would seem that only main regional center should be so linked, in order to permit sufficiently high channel capacity to obtain requisite revenue. Interconnection between satellites, or between satellites and regional centers would seem unlikely. These would not require a multiplicity of trunk circuits, and it is unlikely that the low channel capacity demanded would justify the cost of the scatter link.

The Price of Effective Design Error

It is basic to the concept of system planning that an estimate should be made of expected performance. There is always, of course, a difference between this prediction and the results achieved in the field. This is referred to here, generically, as the "effective design error" although it is apparent that the differential is not, in the precise meaning of the word, due to an error. This effective error accumulates for the following reasons:

1. Malicious intent
2. Incompetence
3. True errors in the data used by design engineers
4. Statistical deviations in empirical material
5. Approximations
    a. Mathematical
    b. Graphical
6. Variations in equipment performance
7. Estimates where there is inadequate information

Modern business could not function if items 1 and 2 were at all significant and the discussion therefore encompasses only the remainder. A substantial effort is made in general to reduce the importance of item 3 so that ordinarily only items 4–7 are of prime importance.

The degree to which an attempt is made to reduce the error depends to a great deal on the risk involved, risk usually being measured in terms of reputation and capital cost.

However, even where the risk is relatively small, there is, concomitant with the scientific method, an attempt to reduce this to reasonable proportions. In fact one of the principal present commercial difficulties is to persuade engineers to provide designs which do not call for performance in excess of risk error.

The minimum value to which the effective error can be reduced, at the present state of the art, is not well established. Even with the best care possible it does not seem reasonable to expect that path attenuation, including fade margin, can be predicted closer than ±3 db even when supported by field data. The figure is, in fact, somewhat less than the most probable error indicated by Norton's[4] work. To this must be added the performance variations associated with equipments. Usually engineers must design to one of two broad conditions. Either equipment is purchased on the open market, or else it is manufactured in the organization of which he is a part. In the first case, it is usually impossible to determine statistical performance deviations. In the second, if need arises, these cannot only be determined, but where necessary, can often be reduced by new engineering developments.

For the first condition mentioned it does not seem reasonable to reduce the net effect of all of the variations expected from the various components of a radio link to better than ±3 db. This figure probably can be reduced in the second case, but the extent of this reduction is not readily apparent and is not likely to be very substantial.

On this basis it would seem that the reasonable total minimum effective error is ±6 db. This implies that under the most careful conditions, it is not reasonable to expect the performance in situ to be better than ±6 db from the calculated design and this figure might well be regarded as a minimum design margin. When there is considerable "scatter" in the information, then a value in excess of this can be expected.

The effective error becomes of increasing significance as the basic cost of an installation rises, and it is the true error component of this—which does not become apparent until after initial tests are made—that causes the most difficulty. It is necessary to reduce this to zero, then changes must be made to the installation for this purpose. In the scatter link, the cost rises steeply as the scatter angle increases, due to the use of high power and large antennas. An installation which already has 10-kw transmitters, 60-foot dishes, and quadruple diversity, imposes a prohibitive cost if only a 3-db true error must be corrected.

This question of risk is usually more serious in the case of scatter circuits than for equivalent microwave circuits. This is because the price per db is normally much greater for the former. This implies that, as the basic cost increases, so does the need for a smaller design margin.

Most organizations require a performance guarantee of some kind. In order to minimize the risk an additional design margin is incorporated into the over-all system plan. However, as the basic cost of the link rises, smaller margins are desirable in order to reduce the net capital cost estimate. This problem of design margin is reflected to a considerable degree in the commercial development of any system, and because of the large risk involved, scatter is particularly vulnerable in this respect. When guarantees are involved which are substantially inviolate, there is a further margin added for "unexpected" deviations in performance. Consequently, the tighter the guarantee, the higher the estimated basic cost. It is, perhaps, not realized by those who insist on performance standards, the extent to which not only themselves as a customer, but the industry as a whole is hindered by this problem. There is need for an understanding of this difficulty and a more realistic assessment of real performance requirements demanded for any service. For instance, the tendency to use Holbrook and Dixon[16] curves for purely commercial circuits is open to question. Data relevant to this problem have appeared[9] and more widespread consideration of the design parameters involved is required.

Strategic Considerations

The factors which influence the strategic importance of a circuit are rarely measured in conventional economic terms, and must be judged on a per se basis. It cannot be expected that engineers who have had no direct contact with military problems should have a clear understanding of the strategic impact of any communications method; guidance must come from those skilled in these techniques. The scatter link appears to have some important advantages from the strategic viewpoint.

1. The long span permits a circuit with a minimum number of links, so that there are fewer stations to protect.
2. Contact can be made over very difficult terrain.
3. The required size of the typical installation means protective measures do not impose disproportionate cost.
4. The long span possible permits contact to be established at points which might otherwise be considered impossible.

The high cost of scatter links with large scatter angles is likely to limit to a large extent such circuits to purely military applications. In order to obtain the maximum distance consistent with cost, performance requirements should be tailored to absolute need. A significant parameter is the loading required. There is some evidence that even for full capacity working, the limits used are too high. Signal-to-noise ratio suitable for military working is much lower than required for toll operation and 15 db weighted is probably an acceptable figure. The emphasis is on circuit reliability, particularly since so many circuits are telegraphic; outage time can interfere seriously in this case, while it is not so important in the case of voice. These aspects imply that the bandwidth can be substantially reduced over that normally required, the distortion associated with this being no longer a deterrent factor. On the basis of a 3-channel system using the minimal bandwidth mentioned, and 99%–99% reliability, it would appear from Figs. 3 and 4 that the limiting value

Vol.
Pt. 1
195

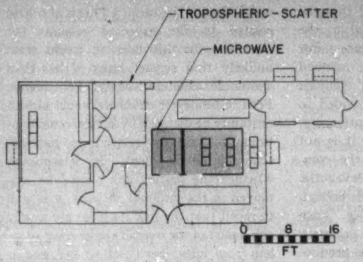

Fig. 8 (left). Relative sizes of microwave and scatter (10 kw) stations

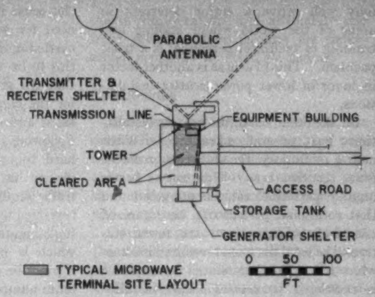

Fig. 9 (right). Relative sizes of microwave and scatter (10 kw and 60-foot dishes) sites

of scatter angle is well over 80 milliradians.

The use of minimal performance standards for strategic circuits generally precludes their use as part of specific toll networks. In a similar way, when part of the national network is justified by carrying strategic circuits, the higher performance requirements limit the range of the military circuit. It is here that a conflict arises which can only be reconciled by the administrations involved.

Significance of the Terrain

Every communication technique must be evaluated with respect to the terrain its spans. This is not simply a matter of the propagation phenomena, but is related to what are primarily factors concerned with logistics and installation. There are of course, cases when the terrain is quite impossible for conventional radio relays but is readily accessible by scatter. The question then is not so much one of relative evaluation as a judgment of its value per se. On the other hand, there are cases where a microwave link can be installed with relative ease, and scatter cannot be proved in. Between these two limiting situations exists the need for a specific assessment of the relative advantage to be gained from the use of scatter. It is probable that a more thorough study of this will eventually yield a critical value of θ versus distance, indicating the "break" point between scatter and microwave links. Certainly it would seem that as θ increases for a given distance, it might be expected that the intervening terrain would be progressively worsening, weighing the balance in favor of scatter.

The scatter link can offer specific advantages which are usually associated with two factors: 1. The long span avoids intermediate stations, and 2. it is frequently possible to have the ends of the link near metropolitan areas. This is particularly true when the scatter circuit is part of a national network. The very nature of the basic requirements of the network virtually dictate that this will be so.

Centers which can be connected by scatter can usually achieve this with a single span. This implies that the terminal installation can be placed relatively near a populated area. This usually means that construction facilities are much more readily obtainable.

The physical area required for the high power installation is quite large compared to the typical microwave station. This is depicted in Fig. 8. However, there is usually considerable freedom in choosing the site, since θ is relatively insensitive to quite large movements of either terminal. The buildings required are much more elaborate for scatter, but this is offset, of course, by the number of stations. The relative problem is indicated by Fig. 9 which shows a typical microwave terminal building, relative to a large θ scatter installation.

Most of the factors which must be taken into account in determining the influence of the terrain can be debated in a similar fashion. The principal factors which must be weighted in the relative evaluation of scatter and microwave systems connecting the same end points are outlined in the following.

1. Survey. Relatively little work over the intervening terrain required by scatter.

2. Antenna direction. Direction of antennas must be precise since relocation can be very costly. However, total number of sitings is less.

3. Location. (Scatter terminals probably near metropolis.) Easier to obtain constructing agencies. Basing and outfitting work crews simpler.

4. Number of stations. Fewer with scatter. Total road length less. Many sites may be difficult of access in microwave system. Logistics during installation phase simplified for scatter.

5. Buildings. Scatter stations more complex, but fewer are required. Total floor area probably greater than microwave, but smaller quantity may simplify construction problems.

6. Site. Scatter terminal requires much larger area than microwave. Usually greater freedom in site choice due to θ insensitivity.

7. Refurbishing stations. Probably easier for scatter particularly when located near metropolis; in severe weather the situation may be under better control.

8. Path loss tests. Scatter equipment likely to be bulky. Tests require relatively long period on single path, so that in a given time the sample of data obtained is more meaningful than the same time spent over several different microwave paths. Also as the number of paths increase, the probability that one may be in error increases.

Operation and Maintenance

The operation and maintenance of a complex unit cannot be divorced from the associated factors of logistics and training. The maintenance of the scatter unit is not simply a matter of supplying trained men. They require special knowledge. In high power installations a whole new field must be covered, dealing with such things as pressured lines, high power diesel generators, and other items peculiar to the installation. Furthermore, this problem is not simply a question of increasing the extent of knowledge. The cost of poor maintenance and operation increases rapidly with the capital cost of the installation. The risk involved to personnel also rises very quickly. These things are not minimized by learning more. Individuals with an increased sense of responsibility are required, and it is well known that the proportion of personnel available decreases rapidly as the demanded level of responsibility rises. Consequently, both knowledge and caliber beyond that required for the conventional radio relay are required. This single consideration may well prove a major deterrent in areas of the world where staffing and training of technical personnel is a basic problem. This of course is another factor in favor of lower power scatter installations.

On the other hand, the scatter installation has several advantages. When near a metropolis, the staff can be drawn from the city area. This means better quality personnel can be attracted and that rotational periods can be organized effectively. Since there are fewer stations, the total personnel required is somewhat less. Further, since maintenance is restricted to central locations, difficulties which are concomitant with bad weather servicing are minimized. Similarly problems associated with dust infiltration and the effects of rain, snow and ice are greatly reduced.

Also related to this question is one of logistics. When the scatter link is associated with other radio links, additional spares have to be kept for the one link alone. This may not seem a great difficulty, but does pose an additional problem of storing, cataloguing, and replacing the special items necessary. This would be greatly simplified if the scatter frequencies could be similar to those of the associated radio links, since it is conceivable that much of the equipment would be common. However, if the question of interference precludes this, as is usually the case, there may be quite large differences in basic equipment and special supplies are necessary. As against this, refurbishing the commensurate microwave system, often occurs at almost inaccessible sites, and in bad weather this may outweigh the disadvantages which are attributable to the scatter installation.

Economic Evaluation

The need for disassociated groups of people to communicate with each other is bound up in an intricate way with their ethnic and economic interdependence. When the intervening terrain is such that scatter seems preferable to other accepted methods of communication linkage there is the implication that this terrain is inimical to the social intercourse of the groups. Thus it must be realized that the scatter link will join semiautonomous groups which have become sufficiently sophisticated to reduce their isolation. Since the scatter link primarily eliminates contact with the intervening areas, it must be inferred that the need has arisen for the connected groups to enter into some form of economic relationship. In this sense it may be considered that the need for scatter is proportional to the need for social interdependence. For this to be valid it must also be assumed that the groups are sufficiently complex for the communication link provided to assist and develop this interrelationship. Following this line of reasoning it is not hard to consider that unless the complexity has reached a certain level, the traffic required could not provide enough revenue to justify its presence, since fundamentally it is an economic necessity which is involved. From this premise it must be assumed that there is a minimum number of channels required of the scatter link before it can be proved in. There is no clear pattern as to what this might be, but it is certain that a scatter circuit cannot be justified simply because it would be cheaper than a commensurate microwave link. It is also apparent that this "break through" number will depend both on the degree of social complexity and on the absolute need involved.

It should also be apparent that the degree of group isolation must be related in some way to the value of θ; since large θ over a short distance implies rugged terrain, while large θ over smooth terrain implies great distance. Both of these factors tend to isolate the groups, and therefore their need for interrelationship is even more dependent on social complexity. We may expect therefore that the number of channels needed by the groups might tend to diminish with increasing θ. On this basis, it would seem as though there would be critical θ, beyond which it would be expected that the number of channels demanded would not support the cost of providing them. It is also apparent there must be a minimum θ which is such that intermediate stations would be desirable, mitigating against scatter. Hence it would appear that there is a range of θ values over which the economic factors associated with human development are contributory toward the use of scatter links.

These discussions will be recognized as particularly applicable to the use of the scatter link as part of a national or international network.

In establishing a break-through number it should be considered that the present day structure of any telephone system is based on the cost with which the required components may be constructed. To be acceptable, any single link of the system cannot disturb this economic balance. In general, it would appear that for a radio link to be justified the cost of the multiplex equipment must outweigh that of the ratio. This is of course related to the expected revenue per channel. On this basis it would seem unlikely that scatter links of less than about 24 channels would be feasible. Fewer number of channels would almost centainly be dictated by special considerations not simply related to national economic development. In determining whether the scatter link should be employed in the national network, it is well to recall that the link itself is only a very small part of the overall engineering problem from subscriber to subscriber, and as part of a complex network, comprises only a part of the total cost. This is indicated to some extent in Fig. 1 which shows the separate parts of the subscriber chain.

For these reasons, the engineering difficulties and basic costs themselves are of relatively minor consequence. Judgment has first to be made on the functional value which has been discussed under Applicability. The scatter link may easily be less costly than a commensurate microwave link over the same path, but it may be necessary to make contact with areas along the route and this cannot be done if the scatter link is employed.

Mention has been made of the fact that the justification for scatter is also related to absolute need of separate groups to communicate. This may be related to two factors not yet discussed. Firstly there is one of self preservation, that is, the circuit is required for its strategic value. Secondly there is the need in which the economic assessment is determined not by the interconnected groups themselves but by outside agencies which find financial return from contact with the groups. There are many such cases of course. For instance mining and oil companies may establish links to areas from which wealth can be obtained, but which, due to their own lack of development have not yet made use of this wealth. Summing up these considerations then, it would seem that the prime justification for the use of scatter is deeply rooted in the question of socio-economic interdependence. The categories of circuits for which scatter is feasible are as follow:

1. Circuits to be integrated into the national or international plan. This is dependent on the need for the groups to establish economic bonds.
2. Circuits other than 1.
    a. Needed for their strategic value or for purposes of safety
        1. Military
        2. Weather
        3. Aviation
        4. Emergency in disaster

b. Special circuits established primarily by groups outside those which are actually connected.
   1. International
   2. Commercial organizations such as mining, oil and power companies.

With the need for a scatter link established, it is necessary to evaluate this relative to other possible modes of interconnection. The scatter link has both special advantages and disadvantages and it is the present purpose to outline these rather than arrive at a conclusion as to their importance.

The large θ installation of course has a considerable portion of the cost in capital structures, whereas in the radio relay the proportionate costs of constructional engineering are higher. Scatter has a higher per station operating cost, and in general this will be higher than the commensurate microwave system. Regular replacements of such items as the high power tubes alone, may be regarded as excessively expensive.

Maintenance of the scatter system is easier, but the staff requires training and a sense of responsibility greater than that of simpler systems. Although reliability of the scatter installation is very good, a single fault in a year may outweigh all other maintenance considerations.

Logistics also tend to be more costly and difficult with the large θ installations. Strategic considerations have been discussed separately, but there are similar factors involved even in a purely commercial undertaking. Where contact is to be established over underdeveloped country, there is a real danger of disruption to on the ground facilities. Most communications companies are familiar with this problem so this need not be elaborated here.

The economic justification for the scatter link will be ultimately determined by consideration of these and other factors. For convenience the principal considerations have been outlined as follows:

1. Engineering planning
2. Survey:
   Sites
   Route
3. Construction:
   Roads
   Connecting utilities—sewage, power, etc.
   Site preparation
   Buildings
   Antenna placement
4. Equipment:
   Basic cost
   Installation
   Testing
5. Running cost:
   Administration of system
   Maintenance (Special staff. Staff training)
   Routine component replacement
   Fuel, and or power
   Supply and storage of components
   Cost of an actual breakdown
6. Deliberate disruption of service. This requires evaluation of such factors as:
   Cost of repairing damage
   Loss of revenue during period of disruption
   Cost of ultimately replacing first installed system with one of less vulnerability
7. Revenue:
   Direct on a per channel usage basis
   Indirect, arising from savings in operating costs due to the communications permitted by the link
   Losses due to lack of contact with population on intervening terrain

Most of the difficulties which mitigate against the use of scatter, do so because of the high power required. This implies that the scatter installation would become much more attractive if low power systems could become established and this in turn highlights the need for a real understanding and assessment of operational requirements rather than the present application of dogma.

Reference to Fig. 4 indicates that for the under 24-channel system a 100-watt transmitter should be extremely effective, particularly if techniques of compandors and concentrators are employed. The 100-watt system would probably be too commercially attractive to suffer over much competition from other methods.

Probable power requirements can be based on the details of Figs. 3 and 4 and the related discussions. Assuming the 40-db signal-to-noise figure, and no compandors, probable division would be

1. Under 12-channel capacity...100 watts
2. 12–60....................1,000 watts
3. 60–600..................10,000 watts

The word capacity is used deliberately here, since it permits the use of units equivalent to line concentrators, dependent on traffic activity, to provide more operative channels than the actual capacity.

For cases where lower signal/noise ratio is possible, as in good commercial or minimal military circuits, the number of channels indicated in the foregoing may be multiplied by 2–5, depending upon the limits actually set.

It must be appreciated this is purely an arbitrary division, since higher power may be called for when particularly large θ and few channels are involved. However, as already implied this rapidly becomes unjustifiable from ordinary economic considerations and ultimately one must presume these circuits are determined primarily by strategic factors.

Conclusions

This paper attempts to evaluate the scatter link not so much in terms of performance as in its compatibility with existing communication facilities, and surrounding facets of the social technology and economic structure.

Optimum performance appears to be in the 2,000-mc/sec region although choice of frequency is related to questions of availability and interference. A performance index is defined, which correlates significant system parameters. From this it is recommended, that in order to make the scatter link commercially competitive, the performance should be determined by real rather than idealized requirements. Further, it is suggested there is need for the development of equipment performing much the same function as telephone line concentrators, so that traffic can be matched to channel capacity. Compandors can also be used to advantage. Consideration of these factors indicates that links could be made much more commercially attractive. Significant results appear feasible with as little as 100-watt installations.

The particular characteristics of scatter lends itself to special applications. Strategically, the use of minimal requirements indicates that scatter angles of over 80 milliradians are feasible. In the national network, it appears the scatter link must be restricted to non-alternate backbone routes, and as such, high reliability is called for.

The normal design margins used in planning, tend to raise cost estimates and the increase due to this margin becomes disproportionate as the basic cost rises. Inviolate guarantees produce estimates which are prohibitive commercially. It is recommended that in order to produce costs which would make scatter attractive, there should be a minimal use of rigid guarantees and serious thought should be given to establishing performance parameters related to real operational requirements.

The nature of the terrain greatly affects the evaluation. It is believed there is a critical scatter angle representing the transition from microwave to scatter techniques. In many cases, it can be expected that the scatter installation can be near to a metropolis. This greatly simplifies problems of logistics, staffing, training, and maintenance, and reduces the influence of terrain on the net cost. Maintenance of the large installation requires not only greater knowledge but also an increased sense of responsibility. While this reduces the potential staff available, stations near the metropolis make greater selection likely.

The need for scatter is considered to stem basically from the socio-economic interdependence of groups of people. From this it would appear there should be a critical range of scatter angle values over which scatter is feasible. Furthermore, for the national or quasi-national networh, there is probably a critical number of channels—24 is suggested—required before the link can be justified. Links with fewer channels would be established only for special conditions determined by specific organizations, outside the national sphere. Following this argument, tentative suggestions relating transmitter power to minimal numbers of channels are suggested; it would appear from this that there is considerable utility for the 100-watt installation.

The Numerical Evaluation of Expressions Involving Complete Elliptic Integrals

FREDERICK W. GROVER
MEMBER AIEE

FORMULAS involving the complete elliptic integrals K, E, and Π occur in the calculation of standards of inductance and mutual inductance, in the calculation of the magnetic field components of coils, and in the calculation of the force between coils. Other examples are found in such fields as hydrodynamics, electrostatics, and in certain applications of conformal mapping. The elliptic integrals may appear explicitly in the formulas or the computer may have to evaluate a complicated integral expression which is recognized as elliptic in nature, but in which K, E, and Π do not appear. Especial attention will here be paid to the procedure to be adopted for reducing such expressions to the standard forms.

Expressed in the Legendre nomenclature the complete elliptic integrals are

$$K=\int_0^{\frac{\pi}{2}}\frac{d\varphi}{\sqrt{1-k^2\sin^2\varphi}}$$

$$E=\int_0^{\frac{\pi}{2}}\sqrt{1-k^2\sin^2\varphi}\times d\varphi$$

and

$$\Pi=\int_0^{\frac{\pi}{2}}\frac{d\varphi}{(1+\eta\sin^2\varphi)\sqrt{1-k^2\sin^2\varphi}}$$

in which the modulus k lies between zero and unity, and the parameter η is unrestricted in value.

Calculations from formulas in which appear the complete integrals of first and second kinds only, namely, K and E, are usually made by interpolating their values from the tables of Legendre[1,2] or other existing tables.[3,4] In the case of a single integral, the accuracy of the result is limited only by the number of significant figures in the tabulated values, and by the accuracy of the interpolation process. However, when combinations of K and E occur in a single expression, the result obtained by substituting the tabular values of K and E, and combining them, may be markedly inferior in accuracy to the individual tabular values, due to a near cancellation of the terms. Illustrations of this are given later. In such cases the obvious way of overcoming this difficulty is by calculating K and E to a sufficient number of places to obtain the desired number of places in the result. The classic work of Legendre[1,2] employs the Landen transformation,[5] which gives the integral in terms of one with either greater or smaller modulus. (For the limiting values of $k=0$ and $k=1$, the elliptic integrals are given by elementary integrals.) It is simpler to make use of the agm (arithmetico-geometric mean) sequences of Gauss.[6] The accuracy of the values calculated by these means is limited only by the number of places on the calculating machine. However, there is an obvious advantage if the expression involving K and E can be made to depend upon the calculation of a single integral, as is illustrated in the following.

Paper 58-777, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted February 18, 1957; made available for printing April 1, 1958.

Frederick W. Grover is with Union College, Schenectady, N. Y.

In the case that the integral of the third kind Π enters, there is the difficulty that tables of Π do not exist, and if they did, that they would be unwieldly and inconvenient on account of the two arguments, modulus and parameter, which would be necessary. Direct calculation must be made. This has usually been accomplished by formulas in which appear both K and E and also incomplete elliptic integrals of the first and second kind, i.e., elliptic integrals where the upper limit is not $\pi/2$. The formula to be used depends upon the value of the parameter.[7] The required incomplete integrals have usually been obtained by tedious double interpolations in the tables of Legendre.[2] Much more convenient are the formulas for Π derived by King.[8] These employ trigonometric recursion formulas and the accuracy is limited only by the computing tools employed. A disadvantage for machine calculations lies in the necessity for auxiliary tables of natural trigonometric functions. Here also the formula used has to be chosen to apply to the value of the parameter.

A recognition of all these difficulties has had the effect of discouraging the use of elliptic integral formulas for computations. Series expansions of them have been preferred. For the case of inductance calculations, for example, series of hypergeometric nature are available, and also expansions in q series. Careful selection of the former is necessary to obtain sufficiently rapid convergence. The q series are very rapidly convergent but the coefficient of the general term is not known.

In 1938, Bartky[9] derived two important formulas. The first is a quadrature formula of very general scope which includes the elliptic integrals as special cases. Unfortunately, it does not yield values of Π of very great accuracy for the parameter range which is usual in physical problems, because of the rapid curvature of the curve plotted with the ordinates to be summed. However, Bartky's second formula, his equation 36 also applies to elliptic integrals and it employs recursion series which yield any desired accuracy. No auxiliary tables are required and the recursion formulas are well adapted to machine calculation. Bartky placed no especial emphasis on this formula, but it has been successfully employed in the calculation of the Bureau of Standards 3-section standard of mutual inductance.[10]

It was pointed out in 1942, in an informal memorandum by the late Dr. Frank Wenner of the Bureau of Standards, that the evaluation of complicated expressions involving complete elliptic integrals can be made to rest upon the calculation of one or the other of two type integrals, which he denoted by P and Q, or at worst, on their sum. Of these, P is Bartky's integral, his equation 36, and Q is a special case of that. This work has never been published. In the following the writer has developed and generalized this theory and has applied it to routine calculations. The illustrative examples are drawn from problems in the calculation of inductance for which series solutions have been previously made, thus giving a check.

The Integrals P and Q

Bartky's second formula may be written with small changes in nomenclature

$$P=\int_0^{\frac{\pi}{2}} \frac{s_0\cos^2\varphi+r_0p\sin^2\varphi}{\cos^2\varphi+p\sin^2\varphi}\,\frac{d\varphi}{R} \qquad (1)$$

where $R=\sqrt{\cos^2\varphi+n_0\sin^2\varphi}=\sqrt{1-(1-n_0)\sin^2\varphi}$ which, compared with the radical $\sqrt{1-k^2\sin^2\varphi}$ of the Legendre nomenclature, shows that $n_0=1-k^2=k'^2$, k' being the complementary modulus.

The denominator $\cos^2\varphi+p\sin^2\varphi=1-(1-p)\sin^2\varphi$ is recognized as the factor $(1+\eta\sin^2\varphi)$ in the denominator of the integrand of Π, η being the parameter.

The evaluation of P depends upon the following sequences:

1. Placing $m_0=1$, and $n_0=k'$, and $c_0=k$, the gauss agm series is

$$m_1=\frac{1+n_0}{2} \qquad n_1=\sqrt{n_0} \qquad c_1=\frac{1-n_0}{2}$$

$$m_2=(m_1+n_1)/2 \qquad n_2=\sqrt{m_1n_1} \qquad c_2=\frac{m_1-n_1}{2}$$

The arithmetic means and the geometric means converge rapidly on the same limit m_∞, which is known as the arithmetrico-geometric mean.

2. Starting with $t_0=p/k'$, calculate the sequence

$$t_{i+1}=\frac{n_{m+1}(1+t_i)^2}{4m_{i+1}t_i}=\frac{n_{i+1}}{4m_{i+1}}\left(t_i+2+\frac{1}{t_i}\right)$$

and t_{i+1} converges on the limit unity.

3. Starting with r^0 $\quad r_1=\dfrac{s_0+r_0t_0}{1+t_0}$

and, in general, $\quad r_{i+1}=\dfrac{s_i+r_it_i}{1+t_i}$

the sequence $\quad s_{i+1}=\dfrac{s_i+r_i}{2}$

converges to a limiting value s_∞ and

$$P=\frac{\pi s_\infty}{2m_\infty}=s_\infty K$$

For the special case $p=1$, the integral P takes the form

$$Q=\int_0^{\frac{\pi}{2}}(z_0\cos^2\varphi+w_0\sin^2\varphi)\,\frac{d\varphi}{R} \qquad (2)$$

Starting with z_0 and w_0,

$$z_1=\frac{z_0+w_0}{2} \text{ and } m_1w_1=\frac{1}{2}(w_0+k'z_0)$$

and, in general,

$$m_{i+1}w_{i+1}=\frac{1}{2}(m_iw_i+n_iz_i).$$

The sequence

$$z_{i+1}=\frac{z_i+w_1}{2}$$

converges to the limit z_∞ and

$$Q=\frac{\pi z_\infty}{2m_\infty}$$

Integrals Involving K and E Alone

If K alone appears, the well-known result is

$$K=\frac{\pi}{2m_\infty} \qquad (3)$$

The combination $(K-E)$ may also be calculated from the m_i, n_i sequence.[11,12]

$$\frac{K-E}{K}=\frac{1}{2}(k^2+2c_1^2+4c_2^2+\ldots+2^ic_i^2+\ldots) \qquad (4)$$

It is to be noted that $(K-E)$ may also be calculated from the relation $K-E=k^2Q$, with $z_0=0$ and $w_0=1$ in the integral Q. There is little difference in the amount of labor involved in this method and the preceding one.

In the general integral expressed in terms of K and E, each with a different coefficient, it is only necessary to substitute the values

$$K=\int_0^{\frac{\pi}{2}}(\cos^2\varphi+\sin^2\varphi)\,\frac{d\varphi}{R},$$

$$K-E=\int_0^{\frac{\pi}{2}}k^2\sin^2\varphi\,\frac{d\varphi}{R}$$

$$E=\int_0^{\frac{\pi}{2}}(\cos^2\varphi+k'^2\sin^2\varphi)\,\frac{d\varphi}{R} \qquad (5)$$

and to collect terms in $\cos^2\phi$ and $\sin^2\phi$ to determine the coefficients z_0 and w_0, which apply to the form of integral Q, which is appropriate to the problem.

Example 1: The well-known Maxwell formula[13,14] for the mutual inductance of two coaxial circular filaments of radii A and a, with a distance d between their planes is

$$M=4\pi\sqrt{Aa}\left(\frac{2}{k}(K-E)-kK\right)$$

in which the modulus of K and E is $k=2\sqrt{Aa}/\sqrt{(A+a)^2+d^2}$. With the use of equations 5 the terms inside the bracket give

$$\int_0^{\frac{\pi}{2}}\left[\frac{2}{k}(k^2\sin^2\varphi)-k(\cos^2\varphi+\sin^2\varphi)\right]\frac{d\varphi}{R}=kQ$$

$z_0=-1,\ w_0=1$

so that

$$M=4\pi\sqrt{Aa}\times kQ \tag{6}$$

Using equations 3 and 4 yields

$$\frac{M}{\sqrt{Aa}}=\frac{2\pi^2}{km_\infty}[2c_1^2+4c_2^2+\ldots+2^ic_i^2+\ldots] \tag{7}$$

An equivalent equation was found by King.[15]

For two filaments of radii $a=10$, $A=90$, $d=0$, the modulus is $k=0.6$ and the complementary modulus $k'=0.8$. The details of the calculation of the agm sequence are as follows:

$m_0=1$
$n_0=0.8$
$m_1=0.9$
$n_1=0.894427191$
$m_2=0.897213596$
$n_2=0.897209268$
$m_3=0.897211432$
$n_3=0.897211432$
$m_\infty\cong 0.897211432$
$m_0w_0=1$
$n_0z_0=-0.8$
$m_1w_1=0.1$
$n_1z_1=0$
$m_2w_2=0.05$
$n_2z_2=0.049844959$
$m_3w_3=0.049922480$

$c_0=0.6$
$c_1=0.1$
$c_2=2.786404\times 10^{-3}$
$c_3=2.164\times 10^{-6}$
$z_0=-1$
$w_0=1$
$z_1=0$
$w_1=0.111111111$
$z_2=0.055555556$
$w_2=0.055728090$
$z_3=0.055641823$
$w_3=0.055641823$
$z_\infty\cong 0.055641823$

From this

$$Q=\frac{\pi}{2}\,\frac{z_\infty}{m_\infty}=0.097415133$$

$Qk=0.058449080$

and

$$\frac{M}{\sqrt{Aa}}=0.734492799$$

By equation 7, $2c_1^2+4c_2^2=0.020031056$ and, with the use of 7-place logarithms, $M/\sqrt{Aa}=0.7344930$, closely checking the result of the preceding calculation.

If this problem is calculated from the values of K and E taken from the tables of Nagaoka and Sakurai[4] there is found

$$\begin{aligned}K&=1.750754\\E&=1.418083\\\hline \text{Difference}&=0.332671\\2(K-E)&=0.665342\\k^2K&=0.630271\\\hline \text{Difference}&=0.035071\end{aligned}$$

$$\frac{M}{\sqrt{Aa}}=\frac{4\pi}{k}(0.035071)=0.734525$$

Because of the near cancellation of the two terms, this result is uncertain by 1 part in 25,000, although the tabular values are correct to seven places.

The advantage of making the calculation of Q, rather than the employment of the tables is still more strikingly apparent when the same example is solved by Maxwell's second formula[13,14] for the mutual inductance of coaxial circular filaments:

$$M=\frac{8\pi\sqrt{Aa}}{\sqrt{k_1}}[K_1-E_1] \tag{8}$$

The modulus of K_1 and E_1 is $k_1=(1-k')/(1+k')$, which is the modulus next smaller than k in the Landen transformation. For the foregoing example

$$k_1=\frac{1}{9},\ k'^2=\frac{80}{81}$$

Written in terms of the integral Q, equation 8 becomes

$$M=8\pi\sqrt{Aa}\times k_1^{3/2}Q_1 \tag{9}$$

with $z_0=0$ and $w_0=1$ in Q_1.

There is found $m_\infty=0.99690159$, $z_\infty=0.50077641$, $M/\sqrt{Aa}=0.734492799$, which checks the result by the first Maxwell equation.

The value may also be calculated by using equation 4 in equation 8. A 7-place logarithm calculation leads to the result

$$\frac{M}{\sqrt{Aa}}=\frac{12\pi^2}{m_\infty}(0.0061824247)=0.7344929$$

The calculation, using the tables, yields $K_1=1.575679$, $E_1=1.565937$, and consequently $(K_1-E_1)=0.009742$, and $M/\sqrt{Aa}=0.73453$, which is in error four units in the last place.

Inductance of a Cylindrical Current Sheet (Solenoid)

The inductance of a solenoid of radius a, axial length b, and total number of turns N, is given by Lorenz's formula.[16] The end effect of the solenoid is given by

$$\frac{L}{L_1}=\frac{4}{3\pi}\times\frac{2a}{b}\left(\frac{(2k^2-1)E+(1-k^2)K}{k^2}-1\right) \tag{10}$$

in which the modulus of the elliptic integrals is

$$k=\frac{2a}{\sqrt{4a^2+b^2}},\ \text{and}\ L_1=\frac{4\pi^2a^2N^2}{b}$$

Expressed in terms of integral Q, this becomes

$$\frac{L}{L_1}=\frac{4}{3\pi}\times\frac{2a}{b}\left[\frac{Q}{k}-1\right] \tag{11}$$

with $z_0=1$, and $w_0=2k'^2=2b^2/(4a^2+b^2)$.

Example 2: For a single-layer coil, wound on a marble cylinder, to serve as an inductance standard at the Bureau of Standards, the dimensions of the equivalent current sheet are $2a=54.1724$ centimeters, $b=30.5510$ centimeters, the total number of turns being $N=440$.

These dimensions yield the modulus $k=0.871032075$, and the complementary modulus $k'=0.491226143$. The convergent of the agm series $1,k'$ is $m_\infty=m_5=0.723071158$ and, calculating $z_\infty\cong z_5=0.696489721$, there follows $Q=1.51305094$, $Q/k=1.73707833$, $8a/3\pi b=0.752560656$. Therefore $L/L_1=0.554696149$, and $L_1=0.183542152$, so that $L=0.101810125$ henry. This value checks closely with that found in previous work.[17]

Equation 10 gives the inductance as the difference of two terms which correspond to two values of axial distance. This is inherent in the nature of the formula.

Equation 4 could be used in the calculation but this would reduce equation 10 to an unfavorable form; in fact, the elegant expression for coaxial filaments seems to be an exception. In general, for routine computations, expressions involving integral Q are preferable.

This reduces calculation to a simple procedure. The sequence (m_i, n_i) is first calculated from the numbers 1, k'. Then, starting from the given values of z_0 and w_0, z_1 is their arithmetic mean. The arithmetic mean of the calculated values m_0w_0 and n_0z_0 is m_1w_1, and dividing this by m_1 yields w_1. That is, each convergent z_{i+1} is the mean of z_i and w_i, and each product $w_{i+1}\times m_{i+1}$ is the mean of w_im_i and z_in_i. The quantities m_i and n_i are available from the sequence formed from $m_0=1$ and $n_0=k'$.

Other important applications of integral Q are, for the components of the magnetic field intensity, due to a current of I amperes, flowing in a circular filament of radius a. At a point P situated at an axial distance x from the plane of the filament, and at a distance y from the axis, Russell's formulas[18,19] become as follows:

The axial component:

$$H_x=\frac{2NI}{10a\rho_1}\left(\frac{2(1-y/a)}{\rho_2^2}\times E+(K-E)\right)=\frac{4NI}{10a\rho_1}\times Q \tag{12}$$

with $z_0=(1-y/a)/\rho_2^2$, and $w_0=(1+y/a)/\rho_1^2$ in Q.

$$\rho_1^2=(1+y/a)^2+\frac{x^2}{a^2} \qquad \rho_2^2=(1-y/a)^2+\frac{x^2}{a^2}$$

The radial component:

$$H_r=\frac{2NI}{10a\rho_1}\left[\frac{2x/a}{\rho_2^2}-\frac{x}{y}(K-E)\right]=\frac{2NI}{10a\rho_1}\times Q \tag{13}$$

with

$$z_0=\frac{2x/a}{\rho_2^2} \text{ and } w_0=-\frac{2x/a}{\rho_1^2}$$

in Q in equation 13. The modulus of the elliptic integrals is

$$k=\frac{2\sqrt{y/a}}{\rho_1} \text{ and } k'=\rho_2/\rho_1.$$

Maxwell's formula for the mechanical force in dynes,[13,20] exerted between two coaxial filaments of radii a and A, each carrying a current of one ampere, when the distance between their planes is d, may be written

$$F=\frac{\pi r_1 d}{r_2^2}[(4-2k^2)E-4k'^2K]$$

$$=\frac{2\pi r_1 d k^2}{r_2^2}\times Q \tag{14}$$

with $z_0=1$, $w_0=-k'^2$ in Q. The modulus is $k=2\sqrt{Aa}/r_1$, and $r_1^2=(A+a)^2+d^2$ and $r_2^2=(A-a)^2+d^2$.

In Appendix I are given the expressions for certain elliptic integrals in terms of integral Q. These may be useful in certain complicated expressions. The reduced expression in terms of a single integral Q is obtained by combining the terms in $\cos^2\phi$ in the integrand to obtain the value of z_0, and by combining the terms in $\sin^2\phi$, the value of w_0 results.

Complete Integral of the Third Kind

The complete elliptic integral of the third kind Π, may be calculated directly by means of the integral P, with $s_0=1$, $r_0 p=1$, $p=1+\eta$, and therefore $r_0=1/1+\eta$. The parameter η in P is unrestricted in value, except for the case that η lies between -1 and $-\infty$, which requires special treatment.

For this case, placing $\eta=-1/\sin^2\theta$, the value of $\sin^2\theta$, corresponding to the given value of η, is calculated, and then the required integral is found from the relation[21]

$$\Pi\left(-\frac{1}{\sin^2\theta}, k\right)=K(k)-\Pi(-k^2\sin^2\theta, k) \tag{15}$$

This makes the calculation of the required integral depend upon the value of the integral P with the parameter $-k^2\sin^2\theta$ substituted for η.

For most physical applications, the parameter is negative and lies between the limits $-k^2$ and -1. It is therefore customary to write $\eta=-c^2$, so that $p=1-c^2=c'^2$ and $1-p=c^2$.

In most problems Π does not appear alone, but in the combination $(\Pi-K)$ for which P takes the form

$$(\Pi-K)=\int_0^{\frac{\pi}{2}}\frac{c^2\sin^2\varphi}{\cos^2\varphi+p\sin^2\varphi}\times\frac{d\varphi}{R} \tag{16}$$

which is integral P with $s_0=0$, $p=1-c^2$, and $r_0=(1-p)/p=c^2/c'^2$.

A special case of the elliptic integral of third kind is that where the parameter $-c^2=-k^2$. This may, of course, be treated as an integral P with the coefficient $p=k'^2$. However, it is possible to show that this special integral may be expressed in terms of K and E only, and consequently may be calculated also as an integral Q, with appropriate values of z_0 and w_0. In Appendix I are noted certain integrals of this class, together with the coefficients which apply, both for use with integral P and with integral Q.

Integrals Involving (Π−K) and K Alone

Writing

$$I=\alpha(\Pi-K)+\gamma K \tag{17}$$

and substituting equation 16 for equation $(\Pi-K)$ and

$$\int_0^{\frac{\pi}{2}}\frac{d\phi}{R} \text{ for } K$$

and reducing to a common denominator yields

$$I=\int_0^{\frac{\pi}{2}}\frac{\gamma\cos^2\varphi+(\alpha c^2+p\gamma)\sin^2\varphi}{\cos^2\varphi+p\sin^2\varphi}\times\frac{d\varphi}{R} \tag{18}$$

which is integral P with

$$s_0=\gamma,\ r_0=\frac{\alpha(1-p)}{p}+\gamma=\alpha\frac{c^2}{c'^2}+\gamma$$

As an example, the axial component of the magnetic field strength at a point situated in the end plane of a solenoid is [22,23]

$$H_{zs}=\frac{2N}{r_1}(1+c')[K\pm c'(\Pi-K)] \tag{19}$$

where

a = radius of the solenoid
x = length of the solenoid
y = distance of the point from the axis
N = number of turns

$$r_1=\sqrt{(a+y)^2+x^2} \qquad k=\frac{2\sqrt{ay}}{r_1}$$

$$c=\frac{2\sqrt{ay}}{(a+y)} \qquad c'^2=\frac{(a-y)^2}{(a+y)^2}$$

The positive sign is to be used for points with $y<a$, and the negative for points for which $y>a$. Equation 19 becomes

$$H_{zs}=\frac{4aN}{r_1(a+y)}\times P \tag{20}$$

in which $s_0=1$, and $r_0=1/c'$ for $y<a$, and $r_0=-1/c'$ for $y>a$.

Integrals which May Be Expressed by (P+Q)

Making use of the defining equations for P and Q, and reducing to a common denominator, there results the general expression

$$P+Q=\int_0^{\frac{\pi}{2}}\frac{(s_0+z_0)\cos^2\varphi+p(r_0+w_0)\sin^2\varphi+(1-p)(w_0-z_0)\sin^2\varphi\cos^2\varphi}{\cos^2\varphi+p\sin^2\varphi}\times\frac{d\varphi}{R} \tag{21}$$

This expression will be used here to treat the general integral involving K, E, and Π. First, however, will be considered an especially simple case.

Jones' Equation

Jones' equation[24] is for the mutual inductance of a solenoid and a circular filament in its end plane:

$$M=2\pi N(A+a)ck\left(\frac{K-E}{k^2}-\frac{c'^2}{c^2}(\Pi-K)\right) \tag{22}$$

where

N = number of turns in an axial length x of solenoid
a,A = the radii of solenoid and filament

$$k^2=\frac{4Aa}{(A+a)^2+x^2},\ c^2=\frac{4Aa}{(A+a)^2},\ c'^2=\frac{(A-a)^2}{(A+a)^2}$$

Jones' formula was first used by Campbell,[22] page 428, at the National Physical Laboratory to calculate the constant of an absolute standard of mutual inductance. In its use at the Bureau of Standards in determining the constant of the 3-section standard of mutual inductance,[10] its evaluation has been effected by calculating the first term by equation 4, while the second term was calculated from the Bartky integral (integral P here). This procedure gives the constant with any desired accuracy. The two terms have opposite signs, but since one term was two to five times the other, this was unimportant.

The Jones formula may also be treated as a special case of the sum $(P+Q)$, making use of the general equation 21. However, the coefficients of the two terms are so related that a still simpler equation results.

Substituting for $(K-E)$ and $(\Pi-K)$

from equations 5 and 16, there is found

$$\frac{K-E}{k^2}-\frac{c'^2}{c^2}(\Pi-K)$$

$$=\int_0^{\frac{\pi}{2}}\frac{(1-p)\sin^2\varphi\cos^2\varphi}{\cos^2\varphi+p\sin^2\varphi}\times\frac{d\varphi}{R}\qquad(23)$$

and, comparing this with general equation 21, note that, if the relations hold,

$$s_0+z_0=0 \text{ and } r_0+w_0=0\qquad(24)$$

then the Jones formula becomes

$$M=\frac{2\pi N(A+a)ck(P+Q)}{w_0-z_0}$$

$$=\frac{2\pi N(A+a)ck}{w_0-z_0}\frac{\pi}{2}\frac{(s_\infty+z_\infty)}{m_\infty}$$

$$=\frac{\pi^2N(A+a)ck}{s_0-r_0}\left(\frac{s_\infty+z_\infty}{m_\infty}\right)\qquad(25)$$

This equation, which was derived by Dr. Wenner, gives great flexibility of solution. As long as the conditions, equation 24, are satisfied, s_0 and r_0 may be selected at will and, furthermore, check solutions may be made using different assumed values of these quantities, without the necessity of recomputing the (m_i,n_i) and t_i sequences.

Example 3. Campbell's example, with $a=10$, $A=14.5$, $x=10$. From the foregoing dimensions, there are found

$k'=0.414396409$, $c=0.98298732$

$k=0.91009649$, $p=c'^2=0.0337359433$

and the $(m_i\,n_i)$ and t_i sequences are

$m_0=1$	$t_0=p/k'$
$n_0=0.414396409$	$=0.0814098350$
$m_1=0.707198204$	$t_1=3.268967504$
$n_1=0.643736288$	
$m_2=0.675467246$	$t_2=1.392179960$
$n_2=0.674721532$	
$m_3=0.675094389$	$t_3=1.027619144$
$n_3=0.675094172$	
$m_4=0.675094280$	$t_4=1.000185579$
$n_4=0.675094280$	
$m_\infty\cong0.675094280$	$t_5=1.000000008$

The calculation of $(P+Q)$ with different assumptions follows.

1	2	3
$s_0=1,\ r_0=-2$	$s_0=1,\ r_0=-1$	$\frac{c'^2}{c^2}(\Pi-K)$ by P
$z_0=-1,\ w_0=2$	$z_0=-1,\ w_0=1$	$s_0=0,\ r_0=1$
$s_0-r_0=3$	$s_0-r_0=2$	$\frac{K-E}{k^2}$ by equation 4
$s_\infty\cong s_5=0.320355180$	$s_\infty=0.5469034$	
$z_\infty\cong z_5=0.817818682$	$s_\infty=0.2118791$	$\frac{K-E}{k^2}=\frac{\pi}{2m_\infty}(0.6059396)$
sum $=1.138173862$	sum $=0.7587825$	$\frac{c'^2}{c^2}(\Pi-K)=\frac{\pi}{2m_\infty}(0.2265482)$
$\frac{1}{3}$sum $=0.379391287$	$\frac{1}{2}$sum $=0.37939125$	Difference $=\frac{\pi}{2m_\infty}(0.3793914)$
$\frac{P+Q}{s_0-r_0}=0.882760314$	$\frac{P+Q}{s_0-r_0}=0.8827603$	$=0.8827607$

The first column, which is a machine calculation, leads, using the number of turns in Campbell's example,[22] to the value $M=24313.8705$ abhenrys per turn on the secondary, checking Campbell's value closely. The calculations in the second and third assumptions were made by 7-place logarithms.

The General Case

The general equation involving complete elliptic integrals of all three kinds may be conveniently written

$$I=\alpha(\Pi-K)+\beta(K-E)+\gamma K\qquad(26)$$

and, making use of equations 16, and 5, yields the integral

$$I=\int_0^{\frac{\pi}{2}}\frac{\gamma\cos^2\varphi+(\alpha c^2+\beta k^2p+p\gamma)\times\sin^2\varphi+(1-p)\beta k^2\sin^2\varphi\cos^2\varphi}{\cos^2\varphi+p\sin^2\varphi}\times\frac{d\varphi}{R}\qquad(27)$$

Comparing this integral with that of equation 21, shows that the general integral 26 may be represented by $(P+Q)$, if the following conditions are satisfied:

$$s_0+z_0=\gamma$$

$$p(r_0+w_0)=\alpha c^2+\beta k^2p+p\gamma$$

$$(1-p)(w_0-z_0)=\beta k^2(1-p)$$

or

$$s_0+z_0=\gamma$$

$$r_0+w_0=\alpha\frac{c^2}{c'^2}+\beta k^2+\gamma\qquad(28)$$

$$w_0-z_0=\beta k^2$$

The choice of one of the coefficients is arbitrary, provided these relations between the coefficients are satisfied.

Example 4. Mutual inductance of coaxial solenoids: This case has received considerable attention, and the work of Nagaoka,[25] Terezawa,[26] Olshausen[27] and Cohen[28] may be cited. If the radii are a and A, the lengths $2l$ and $2l_1$, and the distance between their centers δ, then the mutual inductance is of the form

$$M=I_1-I_2-I_3+I_4$$

in which the terms are the values of the basic integral, given by Cohen:

$$I=\frac{32\pi nn_1\sqrt{(A+a)^2+\delta^2}}{(A+a)^2}\times$$

$$\int_0^{\frac{\pi}{2}}\frac{\sin^2\varphi\cos^2\varphi(1-k^2\sin^2\varphi)d\varphi}{(1+\eta\sin^2\varphi)\sqrt{1-k^2\sin^2\varphi}}\qquad(29)$$

with the four distances $(d+l+l_1)$, $(d+l-l_1)$, $(d-l+l_1)$, $(d-l-l_1)$ respectively, substituted for δ. In equation 29 n and n_1 are the winding densities. For the case where the solenoids are concentric, as well as coaxial, $I_4=I_1$ and $I_3=I_2$, so that $M=2(I_1-I_2)$.

The numerator of equation 29 is $\sin^2\phi-(1+k^2)\sin^4\phi+k^2\sin^6\phi$ and, expanding the expression by the method given in the Appendix II, there results

$$I=\frac{8\pi nn_1}{3}\times Aa\sqrt{(A+a)^2+\delta^2}\times(P+Q)\qquad(30)$$

in which

$$\alpha=-\frac{3(c^2-k^2)(1-k^2)}{c^4},\ \beta=\frac{c^2(1+k^2)-3k^2}{c^2k^2},$$

$$\gamma=1$$

subject to the conditions $s_0+z_0=1$, $r_0+w_0=-k'^2$, $w_0-z_0=1+k^2-3k^2/c^2$ or, expressed in terms of z_0

$$s_0=1-z_0$$

$$w_0=z_0+(1+k^2)-\frac{3k^2}{c^2}\qquad(31)$$

$$r_0=-z_0-2+\frac{3k^2}{c^2}$$

In the example proposed by Cohen[28] and also treated by Nagaoka,[25] the concentric solenoids have $a=10$, $A=15$, $2l=20$, $2l_1=200$, so that for I_1, $\delta=110$, and for I_2, $\delta=90$.

For the calculation of I_1 the condition equations are

$$s_0=1-z_0$$

$$r_0=-z_0-1.852652259$$

$$w_0=z_0+0.899803537$$

and also

$k^2=0.047151277$	$t_0=0.040977908$
$k'^2=0.952848723$	$t_1=6.610635676$
$-\eta=c^2=0.96$	$t_2=2.190476763$
$p=c'^2=0.04$	$t_3=1.161749596$
$m_\infty\cong m_3=0.988033841$	$t_4=1.005630071$
	$t_5=1.000007880$

$$k^2=\frac{4Aa}{(A+a)^2+\delta^2}$$

$$c^2=\frac{4Aa}{(A+a)^2}$$

Making the calculation for two assumed values of z_0,

$z_0=-0.5$

$s_0=1.5$

$r_0=-1.352652259$

$w_0=0.399803537$

$s_\infty \cong s_7=1.019744972$

$z_\infty \cong z_4=-0.047382082$

$s_\infty+z_\infty=0.972362890$

$z_0=0.5$

$s_0=0.5$

$r_0=-2.352652259$

$w_0=1.399803537$

$s_\infty \cong s_6=0.019744972$

$z_\infty \cong z_4=0.952617918$

$s_\infty+z_\infty=0.972362895$

Using the mean of these values and those for $\delta=90$ also, yields

for $\delta=110$, $\sqrt{12725}\,(P'+Q')=174.3834753$

for $\delta=\;90$, $\sqrt{8725}\;\;(P''+Q'')=143.3159327$

Difference $=\;31.0675426$

These lead to the value $M=6213.50852$ $(4\pi nn_1)$, which confirms the value 6213.52 by Nagaoka's formula and 6213.510 by the Searle and Airey[29] formula, both computed with the use of 7-place logarithms.

An examination of the foregoing values of s_∞ and z_∞ shows that a change Δz_0 in the assumed value of z_0 results in an equal change of Δz_0 in the end value z_∞, and a change of $-\Delta z_0$ in the value of s_∞. This is easily shown to be a general truth, and makes it readily possible to choose z_0 so that z_∞ shall be the larger part of the sum $(z_\infty+z_\infty)$. This has the advantage that, when the values of t_i converge only slowly toward their limit of unity, as in this example, the convergence of the sequence z_i is better than that of s_i. A second calculation of z_∞ and s_∞, with an amended value of the assumed value z_0, on which the calculation is based, adds little to the labor involved, since the value of m_∞ and the values of t_i are unchanged. Also, at the each step of the calculation of the new sequences, z_i and s_i, the values should differ from the previously calculated values by the difference Δz_0 between the two assumed values of z_0. This allows errors of calculation to be easily located.

An examination of the foregoing calculated values shows that if z_0 had been assumed to be $z_0=0.519744977$, and therefore $s_0=1-z_0=0.480255023$, then s_∞ would result equal to zero, and the calculation would have depended upon Q alone. This is in line with the fact that $(\Pi-K)$ may be expressed in terms of K, the factor being $(1-p)/p\times s_\infty''$, where s_∞'' is the convergent of the sequence with $s_0=0$ and $r_0=1$. This procedure is found to confirm the critical value of z_0 just cited, but the labor is not very different, since the sequence s_i'' must be calculated. In addition, by this procedure the advantage of a check calculation is lost.

The Jones' formula may be considered as a special case of the general equation 26 with $\gamma=0$. Taking account of the values of α and β, the condition equations found are $s_0=-z_0$, $w_0=-r_0=1+z_0$, which are included in the more general equations 24.

Appendix I. Some Integrals Which Depend Upon Q for Their Evaluation

With $k=$ the modulus, and $k'=\sqrt{1-k^2}=$ the complementary modulus,

$$R=\sqrt{1-k^2\sin^2\varphi}=\sqrt{\cos^2\varphi+k'^2\sin^2\varphi}$$

$$\int_0^{\frac{\pi}{2}}\sqrt{1-k^2\sin^2\varphi}\times d\varphi=E=Q \text{ with } z_0=1,\ w_0=k'^2$$

$$\int_0^{\frac{\pi}{2}}\sin^2\varphi\times\frac{d\varphi}{R}=\frac{1}{k^2}(K-E)=Q \text{ with } z_0=0,\ w_0=1$$

$$\int_0^{\frac{\pi}{2}}\cos^2\varphi\times\frac{d\varphi}{R}=\frac{1}{k^2}[E-k'^2K]=Q \text{ with } z_0=1,\ w_0=0$$

$$\int_0^{\frac{\pi}{2}}\frac{d\varphi}{R^3}=\frac{1}{k'^2}E=\frac{Q}{k'^2} \text{ with } z_0=1,\ w_0=k'^2$$

$$\int_0^{\frac{\pi}{2}}\frac{\cos^2\varphi}{R^3}\,d\varphi=\frac{1}{k^2}(K-E)=Q \text{ with } z_0=0,\ w_0=1$$

$$\int_0^{\frac{\pi}{2}}\frac{\sin^2\varphi}{R^3}\,d\varphi=\frac{1}{k^2k'^2}[E-k'^2K]=\frac{Q}{k'^2} \text{ with } z_0=1,\ w_0=0$$

$$\int_0^{\frac{\pi}{2}}R^3d\varphi=\frac{1}{3}[2(1+k'^2)E-k'^2K]=\frac{Q}{3} \text{ with } z_0=2+k'^2,\ w_0=k'^2(1+2k'^2)$$

$$\int_0^{\frac{\pi}{2}}R\sin^2\varphi d\varphi=\frac{(2k^2-1)E+k'^2K}{3k^2}=\frac{Q}{3} \text{ with } z_0=1,\ w_0=2k'^2$$

$$\int_0^{\frac{\pi}{2}}R\cos^2\varphi d\varphi=\frac{(1+k^2)E-k'^2K}{3k^2}=\frac{Q}{3} \text{ with } z_0=2,\ w_0=k'^2$$

$$\int_0^{\frac{\pi}{2}}\sin^4\varphi\times\frac{d\varphi}{R}=\frac{(2+k^2)K-2(1+k^2)E}{3k^4}=\frac{Q}{3k^2} \text{ with } z_0=-1,\ w_0=1+2k^2$$

$$\int_0^{\frac{\pi}{2}}\cos^4\varphi\times\frac{d\varphi}{R}=\frac{(2-3k^2)k'^2K-2(1-2k^2)E}{3k^4}=\frac{Q}{3k^2} \text{ with } z_0=3k^2-1,\ w_0=k'^2$$

$$\int_0^{\frac{\pi}{2}}\frac{\sin^2\varphi\cos^2\varphi}{R^3}\times d\varphi=\frac{(1+k'^2)K-2E}{k^4}=\frac{Q}{k^2} \text{ with } z_0=-1,\ \ w_0=1$$

$$\int_0^{\frac{\pi}{2}}\sin^2\varphi\cos^2\varphi\times\frac{d\varphi}{R}=\frac{(2-k^2)E-2k'^2K}{3k^4}=\frac{Q}{3k^2} \text{ with } z_0=1,\ w_0=-k'^2$$

$$\int_0^{\frac{\pi}{2}}\sin^6\varphi\times\frac{d\varphi}{R}=\frac{1}{15k^6}[(8+3k^2+4k^4)K-(8+7k^2+8k^4)E]=\frac{Q}{15k^4} \text{ with } z_0=-4(1+k^2),\ w_0=4+3k^2+8k^4$$

$$\int_0^{\frac{\pi}{2}}\cos^6\varphi\times\frac{d\varphi}{R}=\frac{1}{15k^6}[k'^2(-8+19k^2-15k^4)K+(8-23k^2+23k^4)E]=\frac{Q}{15k^4} \text{ with } z_0=4-11k^2+15k^4,\ w_0=-4k'^2(1-2k^2)$$

Appendix II

For the reduction of the elliptic integral

$$\int_0^{\frac{\pi}{2}}\sum_n\left[\frac{\sin^{2n}\varphi}{(1+\eta\sin^2\varphi)^r}\times\frac{d\varphi}{R}\right]$$

the recursion formula (i) on page 60 of reference 30 will be found useful. For complete integrals this reads

$$-2\mu AV_{\mu-1}+(2\mu+1)BV_\mu-(2\mu+2)CV_{\mu+1}+(2\mu+3)k^2V_{\mu+2}=0$$

in which

$$V_\mu=\int_0^{\frac{\pi}{2}}(m+\sin^2\varphi)^\mu\times\frac{d\varphi}{R}$$

$$A=m(1+m)(1+k^2m)$$

$$B=1+2m(1+k^2)+3k^2m^2$$

$$C=1+k^2+3k^2m$$

For example, with $m=1/\eta$ and $\mu=-1$, $2AV_{-2}=BV_{-1}-k^2V_1$, where the integrals are

$$V_{-2}=\int_0^{\frac{\pi}{2}}\frac{\eta^2}{(1+\eta\sin^2\varphi)^2}\times\frac{d\varphi}{R};$$

$$V_{-1}=\int_0^{\frac{\pi}{2}}\frac{\eta}{(1+\eta\sin^2\varphi)}\times\frac{d\varphi}{R}=\eta\Pi$$

$$V_1=\int_0^{\frac{\pi}{2}}(1+\eta\sin^2\varphi)\times\frac{d\varphi}{R}=\frac{K}{\eta}+\frac{(K-E)}{k^2}$$

With $\eta=0$, $m=0$, $\mu=n$, the general integral $\int_0^{\frac{\pi}{2}}\sin^{2n}\varphi\times d\varphi/R$ may be evaluated.

The evaluation of certain integrals in the text follows.

$$\int_0^{\frac{\pi}{2}}\frac{\sin^2\varphi}{(1+\eta\sin^2\varphi)}\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta}\int_0^{\frac{\pi}{2}}\frac{(\eta\sin^2\varphi+1-1)}{1+\eta\sin^2\varphi}\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta}(K-\Pi)$$

$$\int_0^{\frac{\pi}{2}}\frac{\sin^4\varphi}{(1+\eta\sin^2\varphi)}\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta^2}\int_0^{\frac{\pi}{2}}\frac{(\eta^2\sin^4\varphi-1+1)}{1+\eta\sin^2\varphi}\times\frac{d\varphi}{R}$$

$$=-\frac{1}{\eta^2}\int_0^{\frac{\pi}{2}}(1-\eta\sin^2\varphi)\times\frac{d\varphi}{R}+\frac{1}{\eta^2}\int_0^{\frac{\pi}{2}}\frac{1}{1+\eta\sin^2\varphi}\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta^2}(\Pi-K)+\frac{K-E}{k^2\eta}$$

$$\int_0^{\frac{\pi}{2}}\frac{\sin^6\varphi}{(1+\eta\sin^2\varphi)}\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta^3}\int_0^{\frac{\pi}{2}}\frac{(\eta^3\sin^6\varphi+1-1)}{1+\eta\sin^2\varphi}\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta^3}\int_0^{\frac{\pi}{2}}\left[1-\eta\sin^2\varphi+\eta^2\sin^4\varphi-\frac{1}{1+\eta\sin^2\varphi}\right]\frac{d\varphi}{R}$$

$$=\frac{1}{\eta^3}(K-\Pi)-\frac{(K-E)}{k^2\eta^2}+\frac{1}{\eta}\int_0^{\frac{\pi}{2}}\sin^4\varphi\times\frac{d\varphi}{R}$$

$$=\frac{1}{\eta^3}(K-\Pi)-\frac{(K-E)}{k^2\eta^2}+\frac{1}{\eta}\left[\frac{2(1+k^2)(K-E)-k^2K}{3k^4}\right]$$

Core-Reset Functions in Magnetic-Amplifier Analysis

Part I—A Core-Reset Function

G. C. FETH
ASSOCIATE MEMBER AIEE

THE OPERATION of a magnetic amplifier is described by the differential equations of its physical system. In any analysis of amplifier operation the circuit equations resulting from the application of Kirchhoff's laws possess terms containing the voltages which are induced electromagnetically in the core windings by changing core flux in accordance with Faraday's law, and terms containing the various currents which flow in the windings. In general, a knowledge of the core properties relating instantaneous values of the rate of change of core flux ϕ' and of net mmf (magnetomotive force) F of the currents in the windings is an essential part of a complete description of the physical system.

The common, statically measured magnetic quantities are inadequate to describe core behavior under dynamic conditions of changing flux. Mathematical derivations of the over-all relationship between mmf and rate of change of core flux have been hindered by the excessively complicated mathematical problems encountered and by an inaccurate knowledge of the values of the associated physical constants. Qualitative reference to dynamic effects in magnetic cores is often made in terms of the dependence of the width of the dynamic hysteresis loops upon frequency; however, such expression of these effects tends to obscure the instantaneous relationship between the magnetic variables which describe the core's behavior.

It is the purpose of this paper to develop, consistently with the present understanding of flux reversal in magnetic tapes, a general analytical relationship between instantaneous values of the magnetic variables describing the behavior of tape cores of grain-oriented nickel-iron alloy. The resulting analytical description of core behavior will be used in a companion paper to calculate the performance of various magnetic amplifiers; one such example will be included in this paper as a check on the validity of the reset function.

Variables Describing Magnetic State of Core

The dynamic processes of magnetization in tape cores of grain-oriented nickel-iron alloys are described in reference 1 by means of certain theoretical models. Flux changes are ascribed to the movement of the domain walls separating regions of negative from regions of positive saturation flux density. The application of a sufficiently large reverse mmf to a saturated core brings about the formation of small regions of reversed saturation flux density along the edges of the tape cross section and causes the domain walls thus produced to enlarge and move through the tape; the number of nuclei of flux reversal so formed depends largely upon the magnitude of the applied mmf. The motion of the domain walls is hindered by eddy currents, which flow in conducting paths encircling regions of changing flux density; by spin-relaxation phenomena, whose effect upon wall motion is analogous to viscous damping; and by other effects. On the basis of experimental evidence it was concluded that time derivatives of flux other than the first derivative have no appreciable effects on the magnetization process at power frequencies. In short, it appears that dynamic effects of magnetization are dependent both upon the magnitude of F, which affects the number of places where flux reversal initiates and provides the motivation for domain wall motion, and upon ϕ', which produces eddy current and spin-relaxation effects retarding the flux reversal.

It is quickly recognized that the variables F and ϕ' alone are not sufficient to describe core reset; e.g., for reset at constant mmf many values of ϕ' may occur, implying that F and ϕ' are not uniquely related. From the model it appears quite reasonable that the mmf required to produce a given ϕ' may well depend upon both the location and shape of the domain walls. For instance, at a given value of ϕ', implying a given rate of growth of regions of reversed magnetization, the effects of induced eddy currents may be more or less pronounced, depending upon the eddy current paths, which in turn are affected by the geometry of the domain walls and their proximity to the tape surface and to each other. Generally, the configuration of the domain walls is the essential physical feature which makes the "magnetic history" of a material so important in determining its future behavior. In this light, it would appear that any attempt to describe core behavior must consider the point-by-point flux density distribution throughout the material. However, it remains to be seen whether the accurate knowledge of the domain wall configuration is truly indispensable for fairly modest, practical purposes.

For these purposes, it is desirable that the history of the core be expressed by some clearly defined and easily measured magnetic quantity. The flux ϕ existing in the core at any given instant may well be such a quantity; its usefulness in specifying the saturation flux level is apparent. Identity of domain wall configurations implies identity of fluxes. The reverse is not necessarily true, since equality of fluxes does not imply identity of wall configurations, but it seems not unreasonable that, starting from identical wall configurations (as is the case in reset processes initiated from pronounced saturation) and arriving at equal fluxes, the wall configurations may not differ significantly even for somewhat different reset processes. Hence, core flux may well be accepted tentatively as a quantity embodying the magnetic history of the core for flux-reset processes initiating in saturation; this leads to the simplification that the magnetic state of the core during reset may be expressed in terms of the variables F, ϕ', and ϕ.

Certain restrictions on the use of this simplification are necessary. In flux-reversal processes initiated from flux levels other than saturation, ϕ alone is not likely to embody adequately the implications of core history,[2] which explains the restriction to processes initiating from saturation. If during a reset process the mag-

Paper 57-95, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957. Manuscript submitted October 5, 1956; made available for printing November 21, 1956.

G. C. Feth is with the General Electric Company, Schenectady, N. Y.

This work has been performed in partial fulfillment of the requirements for the degree of Doctor of Philosophy at Carnegie Institute of Technology. The work has been supported both by the General Electric Educational and Charitable Fund through a Coffin Fellowship and by the United States Office of Naval Research. The author wishes to acknowledge the valuable guidance of his thesis supervisor, Prof. L. A. Finzi of Carnegie Institute of Technology.

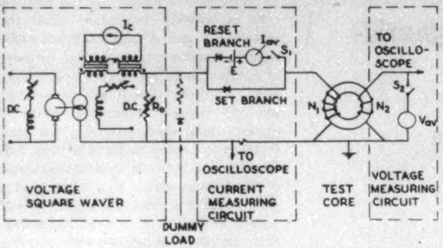

Fig. 1. Test circuit for F_{av} versus ϕ' test

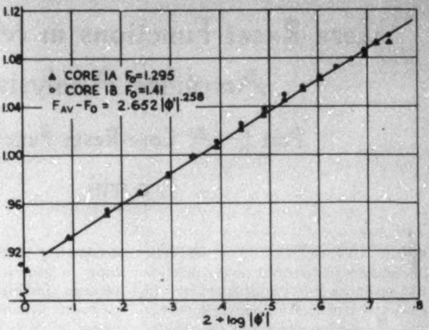

Fig. 3 (right). Log-log plot of F_{av} versus ϕ' test for cores 1A and 1B

nitude of F increases appreciably, additional nuclei of flux reversal may be formed at different times after the initiation of reset and, again ϕ alone may not adequately account for the wall configuration. Thus the restriction to mmf which do not vary radically in time after the beginning of the reset process is necessary. Similarly, if ϕ' should change sign during reset, appreciable upswing of flux is likely to be accompanied by the formation of nuclei of positive flux reversal at the tape surfaces, and again ϕ would not be likely to provide adequate information about instantaneous core behavior. Thus the restriction to monotonic variation of ϕ with time is also necessary. Briefly, any attempt to express core behavior in terms of the variables F, ϕ', and ϕ should be restricted to rather "gentle" processes of flux reset from saturation with core voltages neither unusually large nor excessively fluctuating. These restrictions are fulfilled in many magnetic amplifier circuits; moreover, the use of variables F, ϕ', and ϕ to express core behavior appeared acceptable in reference 3, where data collected with core tests employing steps of mmf were used to predict mmf requirements under quite different conditions.

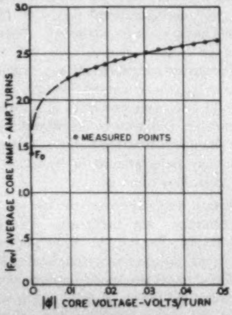

Fig. 2. F_{av} versus ϕ' test for core 1B

Experimentation for Functional Form and Parameters

The problem of expressing dynamic core behavior analytically is one of proper experimentation and interpretation to devise a core-reset function interrelating the instantaneous values of F, ϕ', and ϕ. In concept the simplest way of collecting information about the F, ϕ', ϕ relationship is to measure two of the variables throughout the range of interest for several fixed values of the third variable. This was done in reference 3 by resetting the core from saturation under steps of constant F and presenting the data graphically as ϕ' versus ϕ for various values of F; no analytical formulation of the data was made, however, mainly in view of the irregular shape of these curves.

Dynamic core properties can also be measured by resetting from saturation under constant ϕ' and measuring F versus t; since ϕ varies linearly with time at constant ϕ', these data are readily converted into F versus ϕ. This should yield essentially the same data as the constant-F test, but the constant ϕ' test, using square waves of core voltage, has certain advantages. (The constant mmf test holds no special relation to actual core operation; even in amplifiers where one winding carries a constant control current, the cores seldom experience a step of applied mmf, for there are usually coupled windings in which currents can flow, i.e., through "backfiring" rectifiers, thus modifying the value of total core mmf.) The more or less linear variation of mmf with time observed in the constant ϕ' test suggests rather extensive but not unreasonable simplifications for interpreting and accumulating core data. Thus, for a flux swing from $+\phi_s$, positive saturation, to $-\phi_s$ with ϕ and F linearly dependent upon time (and thus upon each other) the average resetting mmf can be shown to be equal to the mmf when flux is zero. Thus the average resetting mmf F_{av} can be measured under test with a d-c average-reading ammeter connected to carry only the reset current. The F, ϕ', ϕ relationship is then given by the sum

$$F = F_{av}(\phi') + a_1\phi$$

where a_1 could conceivably be a function of ϕ'.

It has been shown[4,5] that for the static properties of toroidal cores with high-grade magnetic materials the approximation that F varies linearly with ϕ is valid over a large part of the range between $+\phi_s$ and $-\phi_s$. In fact, if the static flux-mmf relationship is written as $F = a_0 + a_1\phi$,

* Inside diameter. † Outside diameter. ‡ Ampere-turns.

a_1 is given in terms of the ratio x of inside to outside diameter of the magnetic tape build-up as

$$a_1=\frac{1-x}{1+x}\,\frac{a_0}{\phi_s} \tag{1}$$

Fluxmeter measurements on the several cores used in this work agree rather well with this theoretical value of a_1. No attempt is made in either of the references to derive a theoretical value of a_1 under dynamic conditions. However, data presented in reference 5 seem to indicate that the value of a_1 may increase under dynamic conditions up to about double its static value. However, for practical high-gain cores ($0.7<X<1.0$ approximately) the $a_1\phi$ term comprises a relatively small portion of the total mmf and itself arises from the approximation that the F, ϕ relationship is linear; hence it has been found convenient to assume a_1 equal to the value given by equation 1.

The tests to be described were all performed on cores with windings; thus effects of winding capacitance will be included in the data taken from dynamic tests. However, the coils were progressively wound and separated by tape and the number of turns was kept relatively low to keep capacitive effects small. Test data is not only easier to take when windings are provided but also appears to be more pertinent for actual prediction of the behavior of the wound core. On the other hand, if cores without windings are to be tested, a procedure can be devised for performing the prescribed test on an auxiliary core of known properties provided with convenient windings and coupled to the test core by means of a single turn coil or "permeameter cup"[6] of appropriately low resistance.

The F_{av} versus ϕ' test was performed using the circuit shown in Fig. 1; average resetting currents were measured for various amplitudes of the square wave of core voltage, meanwhile maintaining a constant flux swing slightly less than $2\phi_s$. The emf E in the reset branch is used, if necessary, to ensure that the core is driven into saturation; the dummy load is then used to avoid drawing a direct current component from the square waver. The variable-period square-wave voltage is obtained by shaping the output of a variable-frequency alternator; the shaping is performed by the saturable reactor circuit controlled from a constant current source yielding square-wave gate currents, the desired square wave of voltage appearing across R_0. The actual wave of core voltage with this circuit was "flat-topped" with voltage constant within 1.0% or 2.0% and with a rise time of about 1.0% or 2.0%

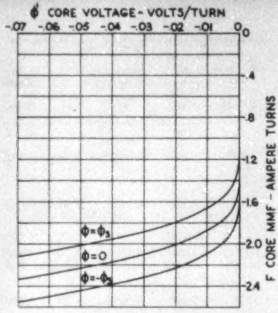

Fig. 7. Plot of core reset function F versus ϕ' for constant ϕ, core 3A

of the duration of the half-cycle. The test circuit operated satisfactorily over a frequency range of 15 to 100 cps. (An alternative means of generating the necessary voltage square waves is offered by transistorized magnetic inverters; here also a variable period and low internal impedance are not difficult to obtain.) The core voltage was measured with a rectifier-type average-reading a-c voltmeter. F_{av} was calculated from I_{av} readings with suitable corrections for any leakage of the rectifiers to obtain the half-cyclic average of resetting mmf.

A typical plot of the F_{av} versus ϕ' test data is presented in Fig. 2. Attempts to fit this data by power series were unsuccessful, but plotting the data in the form log $|F_{av}-F_0|$ versus log $|\phi'|$ led to good fit by a straight line (see Fig. 3) implying a functional form:

$$F_{av}=F_0+a_2(-\phi')^{a_3} \tag{2}$$

F_0 is the value of F_{av} when $\phi'=0$, i.e., the coercive mmf. For the resetting process ϕ', F_0, F_{av}, and a_2 are all negative. F_0 is not evaluated from the F_{av} versus ϕ' test. It could be found from static core tests with a fluxmeter or ballistic galvanometer, but due to the sensitivity of F_0 to core vibrations, Fig. 4, it can be evaluated more accurately under realistic conditions of core usage in terms of the control current of the doubler magnetic amplifier with very low control circuit impedance and using square-wave gate voltage. It was recognized already in reference 7 that under these conditions the postfiring control current corresponds to the static mmf requirement at the flux level of the preset core. In the log-log plot of the results of the F_{av} versus ϕ' test a straight line fits the data fairly well even if there is some error in the value of F_0, and the constants a_2 and a_3 adjust slightly, maintaining good fit of the function to the F versus ϕ' data except at very low values of $|\phi'|$. The complete core-reset function is then

$$F=F_0+a_1\phi+a_2(-\phi')^{a_3} \tag{3}$$

Values of the constants and data for the several cores tested are presented in Table I. Several ways of cross-plotting equation 3 are shown in Figs. 5, 6, and 7.

Simplified Reset Function

Use of the core-reset function (equation 3) in the analysis of amplifiers produces nonlinear differential equations because of the nonlinear relationship between F and ϕ'. Although such equations can be solved, in some cases analytically and in any case by numerical or graphical means, it may be desirable to formulate some simplified functional expression which will lead to more manageable circuit differential equations. In view of the large range of ϕ' in which the F_{av} versus ϕ' relationship departs only slightly from a straight line, Fig. 8, the linearization

$$F=b_0+b_1\phi+b_2\phi' \tag{4}$$

appears feasible when more accurate representation of core characteristics is not necessary, i.e., when only a small portion of the reset time of an amplifier is spent at low values of ϕ'. The variation of F with ϕ is not altered; hence $b_1=a_1$. However, b_0 arises purely from the approximation, not from any physical concept of coercive mmf as did F_0. The ampere turns b_0 and b_2 are determined from the zero intercept and slope respectively of the linearization as indicated in Fig. 8.

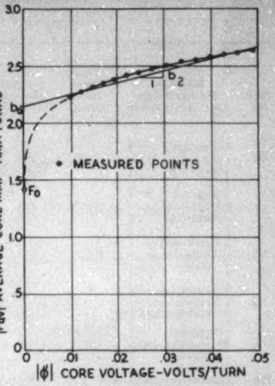

Fig. 8. Linear approximation of F_{av} versus ϕ' data for linearized core reset function

Processes Other Than Reset

The core-reset functions, being limited to reset processes, yield no information about the mmf requirements for ascending fluxes, for the saturated region, or for the transition from descending to ascending flux. Usually amplifiers are designed so as to minimize the effects of prefiring gate currents which flow while flux ascends toward saturation; thus these effects are

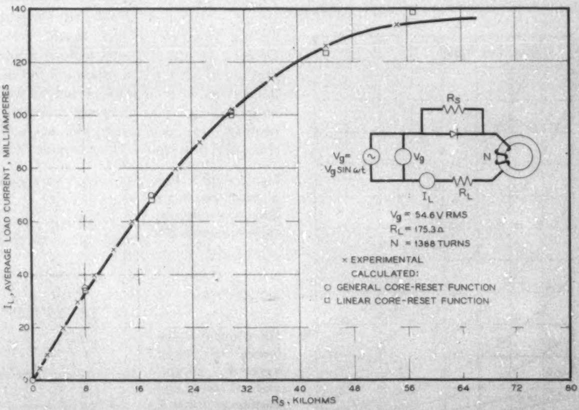

Fig. 9. Circuit and transfer characteristics of resistively controlled, half-wave amplifier

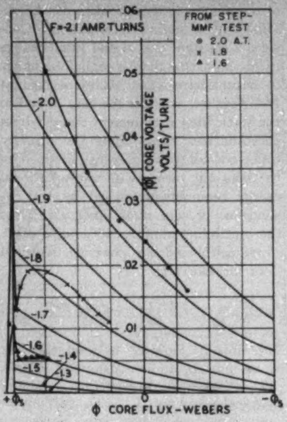

Fig. 10. Comparison of core reset function with results of step-magnetomotive force test, core 3A

often negligible or are satisfactorily approximated in some elementary way. On the other hand, the transition from descending to ascending flux, the bottom of the minor loop, although of limited interest in single-core amplifiers, may be quite important in the analysis of those 2-core amplifiers where a relatively large portion of the reset time is spent in this condition. Similarly, the top of the loop is relatively unimportant in single-core amplifiers at power frequencies. The processes which correspond to the variable slope in this region are thought to be more nearly reversible processes; hence static measurements may suffice when such information is needed. Furthermore, the energy stored during these reversible magnetic processes while gate current is increasing after firing is returned to the circuit as the current recedes, and in some cases where load volt-time integral is the circuit quantity of interest, these effects may go unnoticed. On the other hand, the storage of energy tends to delay the resetting process and some consideration of these effects may be necessary where very accurate knowledge of instantaneous wave forms is necessary or where the voltages induced by the changes of load current during saturation are appreciable.

Check of Core-Reset Functions

A quite significant check of the accuracy and adequacy of the core-reset functions in describing core behavior is afforded by the resistively controlled, half-wave amplifier shown in Fig. 9, for this is a case in which the proper account of ohmic drops during reset is most important. The analysis of the circuit will be deferred to Part II, but the results of the calculations of the transfer characteristics for both reset functions are presented in Fig. 9 showing excellent agreement between the calculated and experimental data.

Response to Step of MMF

The core-reset functions presented were obtained from tests performed under conditions of constant core voltage. It may also be of interest to check whether the reset functions obtained from such tests can be usefully applied to described processes of a somewhat different nature, namely, reset under a constant magnetomotive force F_k. The core-reset function then becomes

$$F_k = F_0 + a_1\phi + a_2(-\phi')^{a_3} \qquad (5)$$

This equation is plotted for several values of F_k and compared with experimental points from the corresponding step-mmf test in Fig. 10. Agreement is by no means perfect, but the discrepancy in values of ϕ' is less than 15% over most of the range of ϕ. The measured curves exhibit an initial spike of ϕ' due to the rapid change of mmf in the saturated region where the ϕ-versus-F slope is greater than zero due to some reversible magnetization of the core; in using the describing function this effect has been assumed away, so no such spike is calculated. The crest of ϕ' appears at ϕ_s when the core-reset function is used, whereas for the experimental data, the crest, aside from the initial spike, occurs at a slightly smaller value of ϕ. On the other hand, the postulation that reset under a step of mmf yields a core voltage which varies sinusoidally in time[8,9] implies that the curves of ϕ' versus ϕ of Fig. 11 would be ellipses with ϕ' being zero at $\phi = \pm\phi_s$ and a maximum at $\phi = 0$. Thus the curves of Fig. 10 are reassuring in that the agreement between calculations from reset functions based on constant-voltage tests and experimentation employing constant mmf is fair. Altogether, the postulated uniqueness of relationship between instantaneous values of F, ϕ', and ϕ appears reasonable for a rather wide range of processes.

Equation 5 can be solved readily for ϕ as a function of time during the constant mmf reset by solving explicitly for $d\phi/dt$, separating variables, and integrating. With the initial condition $\phi(t_0) = \phi_0$ this gives

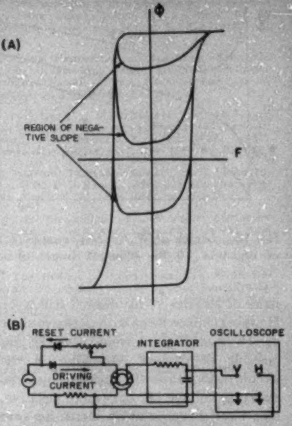

Fig. 11. A—Typical minor hysteresis loops with negative slope dϕ/dF of the resetting branch (Orthonol). B—Resetting circuit. (Reproduced by permission of Magnetics, Inc., from Catalog TWC100.)

$$\phi(t) = \frac{1}{a_1}\left\{F_k - F_0 + \left[(-F_k + F_0 + a_1\phi_0)^{\frac{a_3-1}{a_3}} + \frac{a_1(1-a_3)}{a_3(a_2)^{1/a_3}}(t-t_0)\right]^{\frac{a_3}{a_3-1}}\right\} \qquad (6)$$

and $\phi'(t)$ is found from equations 5 and 6:

$$\phi'(t) = \left\{\frac{a_1(1-a_3)}{a_2 a_3}(t-t_0) - [-\phi'(t_0)]^{a_3-1}\right\}^{\frac{1}{a_3-1}} \qquad (7)$$

Magnetic Hysteresis Loops

Common representations of the flux-mmf relationships of magnetic materials by hysteresis loops has led in some instances to the acceptance of these loops as the only possible locus of values of ϕ and F, or, in other instances, to the acceptance of certain major hysteresis loops taken under particular conditions of applied voltage or current as the basic core relationships. A plausible extension of this reasoning suggested that minor loops had the same sides as those of the major loop with top and bottom of the loop being

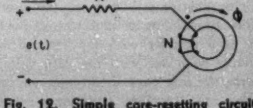

Fig. 12. Simple core-resetting circuit

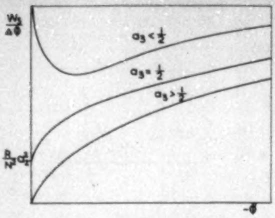

Fig. 13. Sketch of $W_s/(-\Delta\phi)$ versus $(-\phi')$ of equation 10 for different ranges of a_3

more or less flat at the desired flux level. However, minor loops with negative slope $d\phi/dF$ as in Fig. 11 would then be impossible to explain. Actually, in the circuit of Fig. 11 as the applied sinusoidal resetting voltage becomes more negative, core reset proceeds at an increasing rate requiring correspondingly more negative core mmf. As the resetting voltage levels off and becomes less negative the reset slows down and core mmf becomes less negative; as the voltage approaches zero the mmf passes through the static requirement and beyond to zero. Thus as flux decreases from $+\phi_s$ mmf has become first more, than less negative, giving rise to both positive and negative values of $\partial\phi/\partial F$ because of the changing values of ϕ'. The suggested core-reset functions offer approximations of basic core behavior which are consistent with this phenomenon.

With an appreciation of the effects of ϕ' upon dynamic mmf requirements it should not be suprising to find that the ϕ-F relationship for reset of cores in some practical circuits is quite irregular. The minor hysteresis loop with a "nick" at the bottom as presented in reference 7 for the doubler circuit is easily explained in terms of the rate of change of flux. Such irregularities of the reset branches of minor hysteresis loops are even more common in 4-core push-pull amplifiers where each core voltage may change greatly when one of the other cores saturates.[10] Similarly, wide fluctuations of core voltage and corresponding variations of resetting mmf can be expected in circuits which employ pulsing supplies.

For some particular purposes major dynamic loops obtained under special cyclic processes (e.g., sinusoidal voltages or sinusoidal mmf) may supply useful information. For instance, the core voltage of a doubler with low control impedance coincides with the gate voltage during the first part of the resetting half cycle, and therefore a dynamic major loop taken with a sinusoidal voltage of the same amplitude and frequency delineates the core mmf requirements during this part of the process.[11] But in more general cases the core voltage during reset may be of a quite different wave form, and such special loops, disguising the instantaneous dependence of F upon ϕ', are misleading.

Power and Energy Considerations

Toroidal tape-wound cores of modern high-permeability magnetic materials are inherently poor devices for storing energy in electromagnetic form, differently from ordinary linear chokes or reactors. As core flux is cyclicly varied by alternately positive and negative applied voltages, the instantaneous power input to the reactor does not change sign (energy always flows into the core) except for the small changes of flux associated with reversible magnetization in the saturated region or in crossing the static loop from one branch to the other. The amounts of energy involved in these reversible effects are usually quite small with respect to the core losses and with respect to the I^2R losses of the associated circuit, and therefore will be considered negligible for this discussion. The hysteresis effects in an electromagnetic system have as mechanical analog Coulomb friction, which also consistently opposes and absorbs energy from the motivating force, never returning energy to the system except as heat. Moreover, the conversion of electromagnetic energy to heat energy occurs on an instantaneous basis as the irreversible eddy current and spin relaxation effects which correspond to a given ϕ and ϕ' take place.

In magnetic amplifier circuits such energy considerations may be important both from the aspect of core heating and of energy requirements of control. For the simple series circuit of Fig. 12 containing a reactor with N turn winding, an emf source of $e(t)$ volts, and a resistor R ohms instantaneous input power is

$$\begin{aligned} p(t)&=e(t)i(t)=i[Ri+N\phi'] \\ &=\frac{R}{N^2}F(t)^2+\phi' F(t)=P_{\text{resistor}}+P_{\text{core}} \end{aligned} \quad (8)$$

where $F(t)=Ni(t)$. Solutions of the circuit for $\phi(t)$ and $\phi'(t)$ with the aid of the core-reset function can be used for power and energy calculations.

The question arises whether in resetting a core by specified change of flux $\Delta\phi$, there may not be optimum values of ϕ' and the corresponding reset time to minimize either the energy dissipated by the resistor or by the core, or the energy output of the emf source. Some indication of the answer to this problem can be obtained in a simplified situation. Consider a constant emf E and small charge in flux $\Delta\phi$ so that there is negligible change in the mmf term $a_1\phi$ and therefore constant ϕ'. Further, consider the core biased to the static mmf requirement $F_0+a_1\phi$ by a constant bias mmf. Here the primary concern is not with the energy supplied by the bias but rather with the additional energy requirement caused by the dependence of core mmf upon ϕ'. Then the controlling mmf F_c is $F_c=a_2(-\phi')^{a_3}$, where $a_2<0$, and the power p_s required from the source is

$$P_s=\frac{R}{N^2}\,a_2^2(-\phi')^{2a_3}+(-a_2)(-\phi')^{a_3+1} \quad (9)$$

The time Δt required to reset the flux by an amount $\Delta\phi$ at constant ϕ' is $\Delta t=(\Delta\phi)/\phi'$, and the energy per unit flux change required for the reset is $W_s/(-\Delta\phi)$:

$$\begin{aligned} \frac{W_s}{(-\Delta\phi)}&=P_s\frac{\Delta t}{(-\Delta\phi)}=(-a_2)\left[\frac{R}{N^2}(-a_2)\times (-\phi')^{2a_3-1}+(-\phi')^{a_3}\right] \quad (10) \\ &=(-a_2)(-\phi')^{a_3}\times \left[\frac{R}{N^2}(-a_2)(-\phi')^{a_3-1}+1\right] \end{aligned}$$

The energy dissipated in the core $(-a_2)(-\phi')^{a_3}(-\Delta\phi)$, increases as $|\phi'|$ increases. The energy absorbed by the resistor, $R/N^2\, a_2^2(-\phi')^{2a_3-1}(-\Delta\phi)$, increases with $|\phi'|$ if $a_3>1/2$ but decreases if $a_3<1/2$. The functional relationship of $W_s/(-\phi)$ to $(-\phi')$ is sketched in Fig. 13 for a_3 less than, equal to, and greater than 1/2, $(a_3>0)$. For $a_3\geq 1/2$ the energy required from the source decreases as $|\phi'|$ decreases, but for $a_3<1/2$ (which is the range found for the seven cores tested) there is an optimum ϕ',

$$(-\phi')_{\text{opt}}=\left[\frac{R}{N^2}(-a_2)\left(\frac{1}{a_3}-2\right)\right]^{\frac{1}{1-a_3}} \quad (11)$$

From the plot of equation 10 for core 1A, Fig. 14, it is seen that the minimum of control source energy extends over a rather wide range of ϕ' for the larger values of R/N^2, and that little additional energy is required for core voltages greater in absolute value than the optimum. At lower resistances the ratio of source energy at large $|\phi'|$ to the optimum energy varies from 1 up to about 5. At extremely low values of $|\phi'|$ the energy requirement is much greater, making reset at such low rates uneconomical of energy. Moreover, in any practical circuit, bias to the exact static requirement for any considerable range of values of resetting flux is impossible, and such additional mmfs as are necessary to satisfy changes in static re-

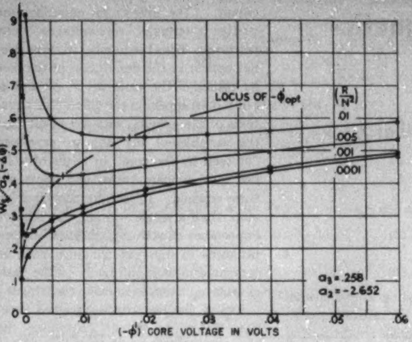

Fig. 14. Source-energy requirement versus rate of core reset for various R/N^2 from equation 10 for core 1A

quirement with flux level will cause increased i^2R losses. These losses become increasingly important as $|\phi'|$ decreases because of the correspondingly longer reset time during which they occur. Thus it seems that where there is a possible choice for wave form of resetting voltages, the choice should be directed away from very small voltages and long resetting times. But in instances where core heating is a problem, some advantage may be found in resetting at fairly low rates of change of core flux to reduce core losses; whether this will result in any appreciable reduction of temperature rise of the reactor will certainly depend also upon other practical considerations such as how much of the resistive power loss occurs in the windings and what is the lower limit on practical values of $|\phi'|$.

Summary

An empircial relationship between instantaneous values of magnetic variables pertinent to the reset of grain-oriented nickel-iron tape cores from initial saturation has been presented in the form of core-reset functions. Care has been taken to keep this information consistent with the physical understanding of the dynamic processes of flux reversal in the magnetic tape and to point out the limitations thus imposed upon its applicability. The postulation that the variables F, ϕ', and ϕ are adequate to express the core reset under certain restrictions has been checked and confirmed. It is recognized only too well that the core-reset functions as developed here do not arise from any general physical theories, and that the constants are not evaluated in terms of basic physical constants; moreover, some error is introduced by the methods and approximations which were found expedient in developing the functions empirically. Yet the formalization of the description of dynamic core behavior allows and motivates more precise thinking and expression of pertinent ideas, adds to the general understanding of the behavior of magnetic amplifier cores, and gives a more concrete basis for magnetic-amplifier analyses.

List of Symbols

a_i—parameters of general core-reset function
a_0—ampere-turns
a_1—ampere-turns per weber
a_2—ampere-turns per volt^{a_3}
a_3—dimensionless
b_i—parameters of linear core-reset function
b_0—ampere-turns
b_1—ampere-turns per weber
b_2—ampere-turns per volt
F—instantaneous mmf, ampere-turns
F_{av}—half-cycle average mmf for reset, ampere turns
F_k—amplitude of step of mmf, ampere-turns
F_0—coercive mmf, ampere-turns
N—number of turns of winding
p—instantaneous power, watts
R—resistance, ohms
t—time, seconds
x—ratio of inside diameter to outside diameter of magnetic tape build-up
W—energy, watt-seconds
ϕ—instantaneous flux, webers
ϕ'—instantaneous time rate of change of core flux, volts = webers per second
ϕ_s—saturation flux, webers

Discussion

H. W. Lord (General Electric Company, Schenectady, N. Y.): This paper defines the symbol F_0 as coercive mmf ampere-turns. However, the value used for F_0 in the analysis is not determined from a major d-c hysteresis loop but from a value of current flowing in the control winding during the postfiring interval in a certain type of magnetic-amplifier circuit.

Since the widely accepted meaning of coercive force H_c is quite different from that actually used for F_0 in this paper, I feel that the paper should define F_0 so as to distinguish it from H_c, the coercive mmf as determined by a major hysteresis loop.

G. C. Feth: Following is a more precise definition of F_0: F_0 for a magnetic core is the value of mmf required by the core in the limit as ϕ' goes to zero at $\phi = 0$ under the condition of reset from saturation in a cyclic magnetization process performed at the particular frequency of interest (here 60 cycles per second).

For cores not sensitive to vibration there may be no noticeable difference between the values of F_0 and d-c coercive mmf. This was actually the case for some of the cores tested. However, a core with one of the greatest per-cent differences between F_0 and d-c coercive mmf was chosen for the data of Fig. 4. For such a core the value of F_0 is quite different from statically measured values and it is wise to make a clear distinction between F_0 and d-c coercive mmf.

Core Reset Functions in Magnetic-Amplifier Analysis

Part II—Determination of Amplifier Performance

G. C. FETH
ASSOCIATE MEMBER AIEE

A CRITICAL analysis of most practical magnetic amplifiers requires a detailed knowledge of the behavior of the magnetic core. For many amplifiers the analysis may be conveniently separated into two parts: determination of the load voltage or current in terms of the extent of the previous reset of core flux from saturation, and determination of the flux reset in terms of the control or input signal. The output may often be evaluated in terms of the preset flux level with only a meager knowledge of core properties, but to determine the value of the controlling variable needed for a given flux reset or to ascertain the effects and optimum values of circuit parameters requires a more extensive understanding of core behavior. The previously published Part I[1] of this paper supplied core-reset functions approximating the relationships between the variables, core flux ϕ, mmf (magnetomotive force) F, and rate of change of flux ϕ', for the process of reset from saturation under certain conditions. In this paper the core-reset functions are contrasted with some other core approximations, several examples of the use of core-reset functions to calculate amplifier performance are shown, and an example of a model theory for the design of analog computers simulating magnetic-amplifier systems is presented.

Reset for Various Core Approximations

Numerous simplifying approximations of magnetic-core behavior are reported in the literature. In Table I five core approximations with various degrees of complexity are presented, and for the simple case of reset from a voltage source in series with a resistor, the differential equations for ϕ as a function of time are formulated and solved, assuming the core to be unsaturated. The applicability of these approximations will be discussed and some particular implications will be examined.

Many magnetic amplifiers are analyzed conveniently in terms of controlling voltages, acting in the control circuit during the reset half-cycle. When the currents which flow to fulfill the mmf requirements of the cores do not produce appreciable voltage drops, no need may be felt for expressing these requirements with any great degree of accuracy; in such cases even the 3-zone idealization, Table I(a), may be satisfactory. However, a better approximation of the core properties is necessary, for instance, to obtain even an estimate of the required current-carrying capacity of the control windings or the power requirements of the control source. For such purposes a slightly less oversimplified idealization such as the square-loop with fixed width, as in Table I(b), may be adequate. With this approximation there arises the practical question of what value to assign to b_0, the half-width of the loop, in order to reasonably approximate the core behavior, for the width of such a loop may well vary by a factor of two or more, depending upon the conditions under which it is measured. Furthermore, both the square-loop and the 3-zone idealizations are inadequate to describe the reset of a core by means of a current source, and any attempt to use them in such analyses is likely to yield highly misleading results. Thus, for general problems of core reset where appreciable voltage drops result from the currents which flow to fulfill the dynamic mmf requirements of the core, more realistic approximations accounting for the effects of ϕ' are needed.

Core approximations which introduce the effects of ϕ' are presented in Table I(c), (d), and (e). Of course, as the approximations become more realistically descriptive of core behavior, the parameters of the core and circuit are more in evidence in the analytical expressions; for the 3-zone idealization N was the only parameter which appeared, whereas for the general core-reset function there are four parameters of the core and two of the circuit. (The differential equations are written in terms of "core voltages," volts per turn. Thus the number of turns does not appear in the description of the core by means of the variables F, ϕ', and ϕ, but it does appear in the differential equations of the circuits, with the result that the variables of any loop are expressed "as seen by the core" in terms of volts per turn, ampere turns, and ohms per turns squared. In fact, for cores bearing more than a single winding the relative importance of voltages, currents, and impedances in different windings may be compared meaningfully only on the basis of such reduction to common turns basis.)

Use of the linearized core-reset function, Table I(c) or (d), containing the parameter b_2, which may be evaluated by direct measurements on the core, establishes a criterion as to the relative magnitude of the impedance of the resetting circuit, and makes possible more meaningful attempts to match the impedance of the signal source plus control winding resistance to an "apparent input impedance" of the core. This is seen directly from equation 6 of Table I; here, in the term (b_2+N^2/R), the importance of the R/N^2 term is determined relative to a fixed property of the particular core, namely $1/b_2$. (The only other term in which R/N^2 appears is in the numerator $[(E/N \div R/N^2)-b_0]$; R/N^2 is associated with E/N since both quantities are parameters of the circuit whereas b_0 is a parameter of the core. Thus, to compare the behavior of the core at different values of R/N^2, the ratio $E/N \div R/N^2$ must be kept constant. This point of view appears reasonable also since $E/N \div R/N^2$ is a significant physical quantity, the mmf acting on the core when there is no flux change.) This relationship of control circuit resistance to $1/b_2$ might, perhaps, also be a useful parameter in some amplifier circuits for determining the relative suppression or constraint of voltages induced in the control loop. Unfortunately, no such simple

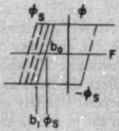
At $e = E =$ CONSTANT

$$\phi' + \frac{b_1}{b_2 + N^2/R}\,\phi = \frac{\frac{E/N}{R/N^2} - b_0}{b_2 + N^2/R} \tag{9}$$

$$\Delta\phi = \frac{1}{b_1}\left[\frac{E/N}{R/N^2} - b_0 + b_1\phi_s\right]\left[1 - \exp\left(\frac{-b_1 T}{b_2 + N^2/R}\right)\right] \tag{10}$$



e. GENERAL CORE–RESET FUNCTION:

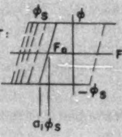
$$F = F_0 + a_1\phi + a_2(-\phi')^{a_3} \text{ FOR } -\phi_s \le \phi \le \phi_s \tag{11}$$

$$\phi' + (R/N^2)a_2(-\phi')^{a_3} + (R/N^2)\,a_1\phi = E/N - (R/N^2)F_0 \tag{12}$$

At $t=0$, $\phi(0) = \phi_s$, $\phi'(0) = \phi'_0$; THEN FOR $e = E =$ CONSTANT:

$$t = \frac{1}{a_1\frac{R}{N^2}}\ln\frac{\phi'_0}{\phi'} - \frac{a_2\,a_3}{a_1(1-a_3)}\left[(-\phi')^{a_3-1} - (-\phi'_0)^{a_3-1}\right] \tag{13}$$

$$\phi = \frac{1}{a_1}\left[\frac{E/N}{R/N^2} - F_0 - a_2(-\phi')^{a_3} - \frac{\phi'}{R/N^2}\right] \tag{14}$$



relationship results from the use of the general core-reset function since no explicit expression for flux reset is forthcoming.

When the value of F depends upon ϕ in the unsaturated core, Table I(d) and (e), the amount of reset depends upon the instantaneous values of applied emf (electromotive force); when F is assumed independent of ϕ the amount of reset depends only on the average emf. For high-gain cores with large inside diameter to outside diameter ratios, the dependence of F on ϕ is not very large, yet its effects are noticeable in some instances. Table I(c) and (d) compare the two effects of neglecting or retaining the variation of F with ϕ. It is, in large part, this dependence of the amount of reset upon the waveforms of applied voltage which causes any application of core information as obtained from a control characteristic under one set of circuit conditions to be of doubtful value for any general analytical purposes. The equations of Table I(d) with b_2 set equal to zero apply for a hysteresis loop with parallel sides of less than infinite slope; however, a 3-zone approximation with less than infinite permeability is not considered here, for it bears no more useful relation to actual characteristics of tape-wound cores than the other approximations and it may actually be quite misleading.

The nonlinear differential equation 12 of Table I(e) describes the reset of a core approximated by the general core-reset function. For a constant applied emf the solution of this equation is obtained by differentiating once with respect to time, separating variables, and integrating. The results are presented in equations 13 and 14; these equations cannot be solved explicitly for ϕ and ϕ' because of the transcendental functional form, but the results may be plotted readily from these two equations for any given values of the circuit parameters. Any general plot or nomogram is excluded because of the large number (7) of independent parameters: F_0, a_1, a_2, a_3, R/N^2, E/N, and ϕ_s.

Although the general core-reset function does not readily lead to simple analytical expressions from which general conclusions may be drawn, yet its use is quite worth while in terms of the accuracy of representing core behavior, especially where large ranges of ϕ' are involved.

As the resistance of the resetting circuit increases, the effects of ϕ' on the mmf requirement become increasingly important. For reset under constant mmf F_K the solutions for $\phi(t)$ and $\phi'(t)$ for the general core-reset function are presented in reference 1; for the linear function the results are obtained from equations 9 and 10 of Table I by replacing $E/N \div R/N^2$ by F_K and N^2/R by zero.

Use of Core-Reset Functions in Magnetic-Amplifier Analysis

In order to analyze a physical system one undertakes to apply physical laws to the system, to express the behavior of each element in terms of suitable approximations, and to determine the mathematical relationships which obtain between the significant variables. In a magnetic amplifier both the magnetic cores and the rectifiers are approximated by discontinuous relationships between the variables, i.e., a rectifier, described in terms of the relationship between current and voltage, has different parameters in the conducting and nonconducting directions, and a core, whose saturation is determined by the level of magnetic flux, is approximated in different ways depending upon whether it is saturated or unsaturated, upon the sign of ϕ', and upon its electromagnetic history. Thus, for analysis, the operation of a magnetic amplifier is separated into intervals during which continuous relationships exist between all variables; the operation is described mathematically for each of these intervals, and the conditions for termination of each interval are established. This completes the mathematical description of the system; from this the steady-state behavior may be found or, with given initial conditions, transient problems may be solved. Such analysis is not particularly simple: numerical analysis may be resorted to,

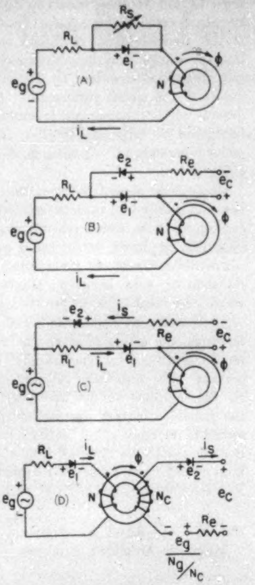


Fig. 1. Single-core single-winding half-wave amplifiers

and the actual solution may well be performed with the aid of digital computers. In some cases, a fair approximation of the features of interest in a particular system may be made without such a complex description of the system.

Here, the approach will be to give some examples of the use of core-reset functions in analysis and to demonstrate the accuracy with which amplifier performance may be calculated. This work is not intended as a detailed analytical treatment of any particular amplifier circuits. Rather, several common circuits will be considered, their various intervals or modes of operation enumerated, the formulation and solution of the mathematical problem described briefly, and the results presented and discussed. Where worth-while simplified approximations of the over-all behavior are forthcoming, they will be described and the results presented. Only resistive loads will be considered, for the problem of determining the effects of the load upon the output is often a fairly straightforward problem[2] which may be treated separately from the problem of determining the amount of flux reset in terms of the control quantity, the latter being of primary interest here since the core behavior is involved directly.

SINGLE-CORE SINGLE-WINDING HALF-WAVE AMPLIFIER

The single-core single-winding amplifier shown in Fig. 1(A), (B), and (C) provides a convenient starting point for analysis of magnetic amplifier circuits, for it avoids problems of coupling between windings and the attendant possibility of recifier "backfiring." The controlling element may be either a signal voltage or a variable impedance, e.g., a photoresistor, or a combination of both. In the operation of the amplifier the output volt-time integral during a gating half-cycle is the difference between the half-cyclic integral of gate voltage and the volt-time integral $N(\phi_s-\phi_p)$ absorbed by the core during reset, where ϕ_p is the preset flux level found at the beginning of that particular gating half-cycle. The rate of reset of core flux depends instantaneously upon the other voltages appearing in the circuit: the supply voltage, the signal voltage, voltages appearing across rectifiers, resistors, or other components. In some particular instances the voltages that affect the reset most significantly do not depend strongly on the currents flowing in the loops; in such cases, of course, no accurate knowledge of the values of these currents is required. But in the situation of Fig. 1(A) control depends basically upon the voltage drop of the resetting current in the controlling resistor R_s, and the voltage equation of the resetting loop is

$$N\phi'=e_g-(R_L+R_s)i \qquad (15)$$

Expressing the instantaneous core mmf requirement by means of the general core-reset function, equation 11, Table I, leads to the following differential equation of reset for sinusoidal gate voltage, $e_g=E_g \sin \omega t$:

$$\phi'+a_2\frac{R_L+R_S}{N^2}(-\phi')^{a_3}+a_1\frac{R_L+R_S}{N^2}\phi =\frac{E_g}{N}\sin \omega t-\frac{R_L+R_S}{N^2}F_0 \qquad (16)$$

This is a first-order, nonlinear differential equation, and may be solved for given values of the parameters by numerical or graphical means. (In particular, a step-by-step numerical solution for ϕ can be found by assuming successive values of ϕ', calculating for each value of ϕ' the corresponding value of ωt with the use of the original flux value, and recalculating ωt with an intermediate value of flux.) Thus ϕ_p can be calculated, and the average value of load current is

$$I_L=\frac{E_g}{\pi R_L}-\frac{\omega N(\phi_s-\phi_p)}{2\pi R_L}-\frac{E_f}{2R_L}-\frac{|I_{\text{reset}}|}{2} \qquad (17)$$

where E_f is the rectifier forward drop and I_{reset} is the half-cyclic average of resetting current flowing through the load in the reset half-cycle. These corrections are often quite small. In Fig. 2 the comparison of the results of these calculations with the measured transfer characteristic of a given amplifier shows excellent agreement.

Use of the linear core-reset function, equation 8 of Table I, yields the following linear differential equation of reset

$$\phi'+\frac{b_1}{b_2+\dfrac{N^2}{R_L+R_S}}\phi=\frac{E_g/N}{1+b_2\dfrac{R_L+R_S}{N^2}}\times \sin \omega t-\frac{b_0}{b_2+\dfrac{N^2}{R_L+R_S}} \qquad (18)$$

which may be solved, with the proper initial conditions, for the preset value of flux ϕ_p existing at the termination of reset near the end of the reset half-cycle. I_L is then evaluated from equation 17. The calculated points of the transfer characteristic with this core approximation also show quite good agreement with the experimental data; see Fig. 2.

If a square hysteresis loop with fixed width, Table I(B), is assumed for the core, the differential equation of reset becomes

$$\phi'=\frac{E_g}{N}\sin \omega t-h_0\frac{R_L+R_S}{N^2} \qquad (19)$$

This equation may be integrated directly and ϕ_p evaluated. There is some uncertainty as to the value of h_0 which is to be used with the square-loop approximation. Calculations were made for three possible values of h_0, i.e., h_0 corresponding to the coercive mmf F_0, to the width of the 60-cycle normal-sinusoidal-voltage dynamic loop at zero flux; and for $h_0=b_0$. The variation in predicted output under use of $h_0=F_0$ or h_0 equal to the dynamic 60-mmf requirements was in the ratio of about 1 to 2, with the actual experimental value lying between these two limits, as would be expected. In this instance it was found that the values calculated for $h_0=b_0$ give good agreement over a large part of the range of control. This may well be partly the result of cancellation between errors caused by neglecting the variation of F with ϕ and of F with ϕ', which errors produce opposite effects over part of the range. If the square-loop approximation is to be used, it seems that the value chosen for h_0 might just as well be selected as b_0, i.e., the value of F found by extra-

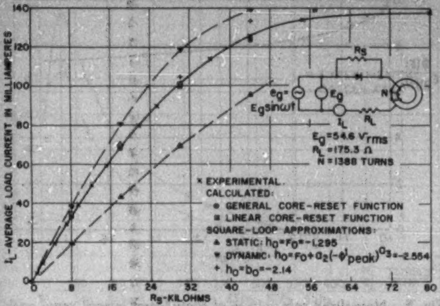

Fig. 2. Transfer characteristic of resistively controlled single-core single-winding half-wave amplifier for normal voltage, core 1A

polating the F_{avg} versus ϕ' curve to zero ϕ' by means of a straight line approximation of the curve at large ϕ'; see reference 1. Evidently the choice of the type of core approximation to be used depends on the accuracy of predictions needed in any particular instance. It may well be recognized that any idealization of core behavior different from the trivial 3-zone representation involves certain analytical complications.

Some single-core half-wave amplifiers employing a separate winding for control have the same differential equations as a single-winding amplifier (if perfect coupling between windings is assumed). For instance, in the amplifiers of Fig. 1(C) and (D), by comparing corresponding equations of the gate loop, control loop, and mmf in the two cases it can be shown that, for identical gate circuit parameters the two circuits are identical if

$$e_c^* = (N_c/N)e_c$$

$$e_s^* = (N_c/N)e_s$$

$$i_s^* = (N/N_c)i_s$$

$$R_s^* = (N_c^2/N^2)R_s$$

[where the variables with * refer to Fig. 1(D) and the others to Fig. 1(C)], these being the reflected-value transformations of ordinary transformer techniques. Thus the same analysis as for the single-winding amplifier applies also to such circuits. The many similar circuits, built up with more windings and perhaps more cores, where voltages are added and subtracted in various ways to perform the desired control, may also be analyzed with the use of the core-reset function to supply the necessary information about the currents and associated *IR* drops resulting from the core mmf requirements. In particular, analyses may be made for the practical case of source impedances different from zero.

SINGLE-CORE MULTIPLE-WINDING HALF-WAVE AMPLIFIER

As an example of the single-core multiple-winding half-wave amplifier the operation of the 2-winding amplifier of Fig. 3 with constant control voltage E_c and control resistance R_c will be considered. In the positive half-cycle of gate voltage the core is brought to saturation, firing at the angle α. The core remains saturated until the angle β $(\beta \le \pi)$ when the core mmf, $N_gi_g+N_ci_c$, (with i_c negative) becomes equal to the static mmf requirement of the resetting branch. The rectifier is still in the state of forward conduction; thus the voltages appearing in both control and gate loops affect the core reset. At the angle $\gamma(\gamma \ge \pi)$ the rectifier voltage becomes negative and the rectifier blocks. In the interval $\pi \le \omega t \le \gamma$ the gate current is quite small; prior to π the core voltage is practically zero, and after π it is limited essentially to e_g/N_g(i.e., one may say that the core voltage is "gate-limited" and the interval $\beta \le \omega t \le \gamma$ is the first interval of gate-limited reset). After γ the core is reset under the influence of the control circuit alone until the rectifier voltage again becomes positive at δ $(\delta \le 2\pi)$; this marks the beginning of a second interval of gate-limited reset. The core continues to reset with core voltage practically equal to e_g/N_g (assuming that negative saturation is not reached) until the gate voltage again begins raising the flux toward saturation; this occurs at some time after 2π. In steady state the cyclic-average load current I_L may be found by integrating the gate circuit differential equation to obtain

$$I_L = \frac{E_g}{2\pi R_L}(\cos\delta - \cos\gamma) + \frac{\omega N_g}{2\pi R_L} \times [\phi(\delta) - \phi(\gamma)] - \frac{E_f}{2\pi R_L}(\pi + \gamma - \delta) \quad (20)$$

for $E_g \le E_{gN} = \omega N_g\phi_s$. Between γ and δ core voltage may be determined from the control-loop voltage equation and the core-reset function; the initial conditions are: $\phi'(\gamma) = (E_g/N_g)\sin\gamma$, $\phi(\gamma) = \phi_s - (E_g/\omega N_g) \times (1+\cos\gamma)$. For large values of R_c/N_c^2 and small amounts of reset $|\phi'|$ will be small, and to avoid introducing errors the general core-reset function should be used. Thus equation 12 of Table I is the differential equation for reset by control, $\gamma \le \omega t \le \delta$. The angle γ is evaluated by substituting the values of $\phi'(\gamma)$ and $\phi(\gamma)$ into this equation and solving the resulting transcendental equation for γ:

$$-\sin\gamma = \frac{R_c}{N_c^2}\left[a_3\left(\frac{E_g}{N_g}\right)^{a_3-1}(-\sin\gamma)^{a_3} + \frac{a_1}{\omega}\left(\frac{\omega N_g\phi_s}{E_g} - (1+\cos\gamma)\right) + \frac{N_gF_0}{E_g}\right] - \frac{E_c}{N_c}\,\frac{N_g}{E_g} \quad (21)$$

Solution of the differential equation and use of the defining relationship

$$\phi'(\delta) = \frac{E_g}{N_g}\sin\delta \quad (22)$$

yields the following transcendental equation for δ:

$$\delta = \gamma + \frac{\omega}{a_1}\,\frac{a_3(-a_2)}{1-a_3}\left(\frac{E_g}{N_g}\right)^{a_3-1}[(-\sin\delta)^{a_3-1} - (-\sin\gamma)^{a_3-1}] + \frac{N_c^2}{R_c}\,\frac{\omega}{a_1}\ln\left(\frac{\sin\gamma}{\sin\delta}\right) \quad (23)$$

$\phi(\delta)$ can be evaluated from equation 12 and I_L from equation 20. A few calculations on the basis of these equations show quite close agreement with the experimental control characteristics shown in Fig. 4.

In view of the fairly good linearity of the control characteristics presented in Fig. 4, it appears worth while to concentrate some effort on estimating two points which will determine a satisfactory straight-line approximation. The control mmf which just produce full output and quiescent output might at first glance appear to be the simplest to approximate. However, at the verge of resetting, $F = F_0 + a_1\phi_s$, and this point as plotted in Fig. 4 at full output does not lie satisfactorily close to the linear approximations of most of the characteristics. Poor agreement

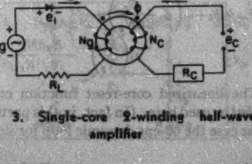

Fig. 3. Single-core 2-winding half-wave amplifier

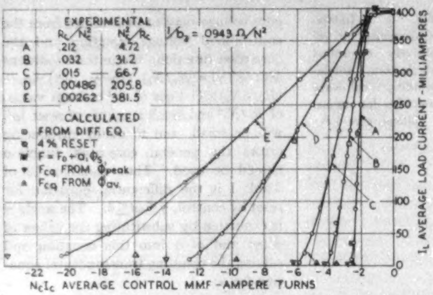

Fig. 4. Control characteristic of single-core 2-winding half-wave amplifier with various R_c/N_c^2 and normal voltage, core 1A

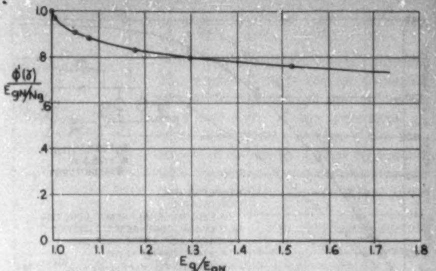

Fig. 5. Normalized core voltage of control-reset interval versus peak gate voltage for $E_g \geq E_{gN}$

here is not surprising, for this is in the range of very small reset from saturation where the core-reset function is not a very accurate approximation (since any curvature of the top of the loop has been ignored). This difficulty may be bypassed by making a rough approximation of the mmf required to reset the flux by a few per cent of $2\phi_s$. For instance, assume a constant ϕ' throughout the resetting half-cycle so that the flux will be reset by 4% of $2\phi_s$; then $\phi'_{(4\%)} = 0.04\ (4f\phi_s)$ and the average mmf requirement is

$$F_{4\%} = F_0 + a_1(0.96\phi_s) + a_3(0.16f\phi_s)^{a_3} \qquad (24)$$

The point thus calculated for Fig. 4 is in better agreement with the linearizations of the transfer characteristics.

For the calculation of the mmf F_{cq} which brings about the minimum or quiescent output either of two approximations appears feasible.

The one approximation considers the most critical requirement on E_c. Thus, for minimum output and for $E_g \leq E_{gN} = wN_g\phi_s$ the resetting core voltage essentially equals e_g/N throughout the reset half-cycle; then the peak value of $/\phi'/$ occurring at $3\pi/2$ is E_g/N_g, the value of flux is $\phi_s - E_g/wN_g$, and the mmf requirement at this instant may be evaluated from the core-reset function, equation 11. The control voltage required to produce these instantaneous values of F_c and ϕ' simultaneously may be evaluated from the control circuit voltage equation; the corresponding average control mmf F_{cq} is then

$$F_{cq} = F_0 + a_1\left(\phi_s - \frac{E_g}{\omega N_g}\right) + a_2\left(\frac{E_g}{N_g}\right)^{a_3} - \frac{E_g}{N_g}\,\frac{N_c^2}{R_c} \qquad (25)$$

The linearized core-reset function could also be used here. (In fact, in this particular case the 60-cps dynamic loop for sinusoidal voltage for proper value of E_g could be used; this is not true, however, in the following case.) For $E_g > E_{gN}$ minimum output results from flux reset to negative saturation. Then the core voltage is gate-limited during only a part of the resetting half-cycle, π to γ and δ to 2π, and is determined by the control circuit alone between γ and δ. Assuming that core voltage is constant between γ and δ, the most critical requirement on E_c occurs at δ. By equating the integral of core voltage in the resetting half cycle to $(-2\phi_s)$ γ, δ, and ϕ' in the interval γ to δ may be evaluated in terms of E_g/E_{gN}; a normalized curve for $\phi'(\gamma)$ is presented in Fig. 5. Assuming $\phi(\delta)$ is approximately zero, the value of F_{cq}, as determined by the critical requirement on E_c, may be found from Fig. 5 and the following equation:

$$F_{cq} = F_0 + a_2[-\phi'(\gamma)]^{a_3} + \phi'(\gamma)\frac{N_c^2}{R_c} \qquad (26)$$

Another possible means of approximating F_{cq} is to compute the average value of ϕ' over the reset half-cycle for the condition of minimum output and to use this value ϕ'_{avg} to approximate the critical value of E_c and the value of F_{cq}. Thus, for $E_g \leq E_{gN}$ and $\phi'_{avg} = 2E_g/(\pi N_g)$,

$$F_{cq} = F_0 + a_1\left(\phi_s - \frac{E_g}{\omega N_g}\right) + a_2\left(\frac{2E_g}{\pi N_g}\right)^{a_3} - \frac{2E_g}{\pi N_g}\,\frac{N_c^2}{R_c} \qquad (27)$$

and for $E_g \geq E_{gN}$ and $\phi'_{avg} = 4f\phi_s$,

$$F_{cq} = F_0 + a_2(4f\phi_s)^{a_3} - 4f\phi_s\frac{N_c^2}{R_c} \qquad (28)$$

Values of F_{cq} are plotted in Fig. 4 for normal gate voltage for each of these approximations. Agreement is best at large values of R_c/N_c^2; the first approximation gives conservative estimates of the slope of the characteristic whereas the second approximation yields optimistic values.

Each of these approximations, equations 25 through 28, indicates a linear relationship between F_{cq} and N_c^2/R_c; plots of the measured values of F_{cq}, and values of F_{cq} estimated by linearizing the experimental control characteristics, are both very close to a straight line, as shown in

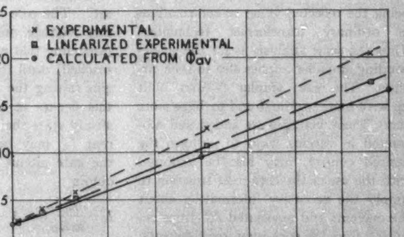

Fig. 6. Average control mmf for minimum output for various N_c^2/R_c, 2-winding half-wave amplifier, core 1A

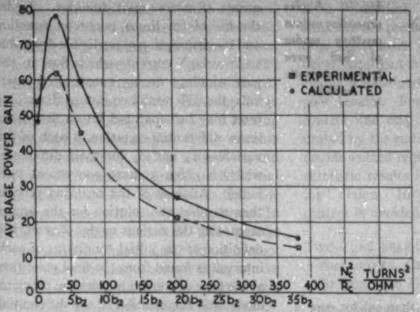

Fig. 7. Power gain versus N_c^2/R_c for 2-winding half-wave amplifier, core 1A

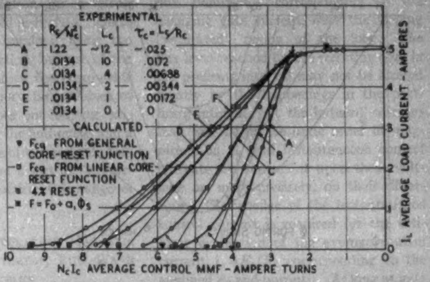

Fig. 8. Control characteristics of the 2-winding half-wave amplifier with inductive-control impedance at normal voltage, core 2A

Fig. 6. Values of F_{cq} calculated with the second of these approximations are plotted also, and lie within 9% of the values estimated by linearizing the control characteristics. Letting A_I represent the current gain of the amplifier or the slope $(dI_L)/(dI_c)$ over the linear portion of the control characteristic, a sort of average power gain $A_p = A_I^2\, R_L/R_c$ may be calculated; this is presented in Fig. 7 and compared with experimental values of A_p determined from the linearized control characteristic. The value of N_c^2/R_c for the optimum value of A_p is indicated fairly well by the calculations. Thus these approximations of the control characteristic have allowed quantitative predictions of the effects of control circuit resistance upon current and power gains and upon the shift of the control characteristic with control circuit resistance.

If inductive impedance is present in the control circuit of this half-wave amplifier it may be quite difficult to determine the various modes of operation simply by inspection. However, for $E_g \leq E_{gN}$ and $(R_c/N_c^2) >> (R_L/N_g^2)$ it is possible to determine critical control circuit conditions for minimum output and thereby ascertain a value for F_{cq}. At the minimum output level ϕ' is essentially equal to e_g/N_g throughout the cycle. Then the voltage equation of the control circuit

$$E_c = R_c i_c + L_c\frac{di_c}{dt} + N_c\phi' \tag{29}$$

may be solved for $F_c(t) = N_c i_c(t)$ to obtain

$$F_c = \frac{E_c/N_c}{R_c/N_c^2} + \frac{E_g/N_g}{R_c/N_c^2}\left(\frac{-\sin \omega t + \omega\tau_c \cos \omega t}{1+\omega^2\tau_c^2}\right) \tag{30}$$

where $\tau_c = L_c/R_c$. The condition that ϕ' just equals the gate voltage per turn can be met by insuring that i_L be greater than or equal to zero at all times so that the gate rectifier never blocks. More precisely, i_L must go to zero with a zero rate of change with respect to time; thus, the critical angle θ and the corresponding value of $F_{cq} = (E_c/N_c)/(R_c/N_c^2)$ may be found from the two conditions: $i_L(\theta) = 0$, $di_L(\theta)/dt = 0$. Approximating the core by the linear core-reset function, the gate circuit mmf is

$$N_g i_L = b_0 - F_{cq} + b_1\left(\phi_s - \frac{E_g}{\omega N_g}\right) + \frac{E_g}{N_g}\left(b_2 + \frac{N_c^2}{R_c(1+\omega^2\tau_c^2)}\right)\sin \omega t - \frac{E_g}{N_g}\left(\frac{b_1}{\omega} + \frac{N_c^2\omega\tau_c}{R_c(1+\omega^2\tau_c^2)}\right)\cos \omega t \tag{31}$$

and the first time derivative is

$$\frac{d(N_g i_L)}{dt} = \frac{\omega E_g}{N_g}\left[\left(b_2 + \frac{N_c^2}{R_c(1+\omega^2\tau_c^2)}\right)\times \cos \omega t + \left(\frac{b_1}{\omega} + \frac{N_c^2\omega\tau_c}{R_c(1+\omega^2\tau_c^2)}\right)\sin \omega t\right] \tag{32}$$

Setting this derivative equal to zero at $\omega t = \theta$ and solving for θ yields

$$\tan \theta = \frac{-\left(1 + b_2\dfrac{R_c}{N_c^2}(1+\omega^2\tau_c^2)\right)}{\dfrac{b_1}{\omega}\dfrac{R_c}{N_c^2}(1+\omega^2\tau_c^2) + \omega\tau_c} \tag{33}$$

and the corresponding value of F_{cq} for $N_g i_L = 0$ in equation 31 is

$$F_{cq} = b_0 + b_1\left(\phi_s - \frac{E_g}{\omega N_g}\right) - \frac{b_2 E_g}{N_g}\times \sqrt{\left(1 + \frac{1}{b_2\dfrac{R_c}{N_c^2}(1+\omega^2\tau_c^2)}\right)^2 + \left(\frac{b_1}{\omega b_2} + \frac{\omega\tau_c}{b_2\dfrac{R_c}{N_c^2}(1+\omega^2\tau_c^2)}\right)^2} \tag{34}$$

(A similar derivation can be performed with the use of the general core-reset function; the results are in slightly more complicated form.) Values of F_{cq} and $F_{4\%}$, found as described previously, are compared with experimental control characteristics in Fig. 8 for various values of τ_c and for normal voltage. The agreement is quite good inasmuch as each calculated value of F_{cq} lies close to or within the range of F_{cq}'s between the experimental and the linearized control characteristics.

HALF-WAVE BRIDGE MAGNETIC AMPLIFIER

The half-wave bridge magnetic amplifier[3] of Fig. 9 is a 2-core push-pull amplifier. In operation both cores are saturated at the end of the positive half-cycle of the alternating supply voltage and are reset in the negative half-cycle under the combined influence of the control mmf $N_c i_c$ and the bias mmf $N_b i_b$. The bias windings consist of only about 10% or 20% as many turns as the gate windings; the bias resistors R_b are needed

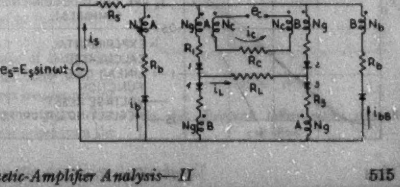

Fig. 9. Half-wave bridge magnetic amplifier

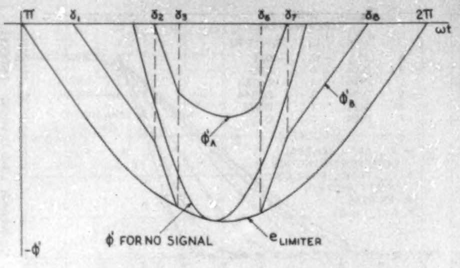

Fig. 10. Angles separating various resetting modes of half-wave bridge magnetic amplifier

to limit the bias currents. The control circuit also must have fairly high R/N^2 in order to limit the currents during the output interval. Thus, in calculating the reset of the cores, the nearly current-source behavior of the bias and the appreciable resistance of the control loop together make necessary a careful accounting of resistive drops; hence, an accurate knowledge of the core mmf requirements is needed.

During each resetting half-cycle there are several different modes of reset of the two cores. For positive signal voltage E_c the reset of core B under influence of bias and control begins at γ_1; core A begins reset later at γ_2; see Fig. 10. The resetting voltage of core B grows until it exceeds the limiting voltage of the source; then rectifiers 2 and 4 begin to conduct initiating an interval of gate-limited reset at γ_3 (γ_3 may occur before or after γ_2). Core A may also experience a gate-limited interval beginning at γ_4 and ending at γ_5, depending upon the bias mmf. The gate-limited reset of core B terminates at γ_6. After the end of the respective gate-limited intervals for each core, reset proceeds under the influence of control and bias until reset ends at γ_7 (which may be greater or smaller than γ_6) for core A, and at γ_8 for core B. In the positive half-cycle of supply voltage cores A and B both absorb voltage, with the two gate windings effectively in series until saturation of core A at α_A; output voltage then appears across the parallel combination of the resistor R_L and the two windings of core B until core B fires at α_B. After both cores have fired the current in the windings is limited primarily by the source resistance R_s. The cyclic average of output voltage is given approximately by

$$E_L = \frac{\omega N_g \Delta\phi}{2\pi\left(1+\frac{R_w}{R_L}\right)} \tag{35}$$

where R_w is the greater of R_1 and R_3, rectifier forward drops are neglected, and $\Delta\phi$ is the difference in preset fluxes of core A and core B and can be either positive or negative depending upon the sign of E_c.

Calculation of $\Delta\phi$ requires the solution the differential equations of reset for all the various modes. The differential equations for each interval are found by applying Kirchhoff's voltage law to the various loops and expressing core mmf by means of a core-reset function. Under the use of the linear core-reset function and the assumption of negligible drops due to "overlap" currents which flow in the gate windings during gate-limited intervals, the differential equations describing reset may be separated into a first-order linear differential equation in each of the variables ϕ_A and ϕ_B (or their difference, which is often a more convenient variable). Analysis of the resetting process then requires the solution for the angles separating the various modes of reset, the definition of the initial conditions of each interval as found from the final condition at the time of transition from the previous mode, and the solution of the differential equations of each interval. No attempt is made here to present a general analytical solution of this problem; a numerical solution was performed for a particular amplifier and the results are compared with the measured control characteristic in Fig. 11. Quite close agreement is obtained; note the poor agreement afforded under assumption of "voltage reset" neglecting i_cR_c.

Fast-Response Even-Harmonic Magnetic Amplifier

The fast-response even-harmonic magnetic amplifier[4,5] of Fig. 12 is a 2-core amplifier which in every half-cycle gives an output dependent upon the control during the same half-cycle; hence the term fast response. The half-cyclic integral of the alternating supply voltage is much larger than the sum of the swings of flux linkages of the N_s windings of the two cores, which are therefore driven into saturation in each half-cycle. At the end of the negative half-cycle of supply voltage both cores are at negative saturation. In the succeeding half-cycle both cores are reset toward positive saturation under the influence of the supply voltage and the control circuit; e_c is positive so that the voltage induced in the load circuit causes the rectifier to block as long as neither core is saturated. Core A reaches positive saturation first

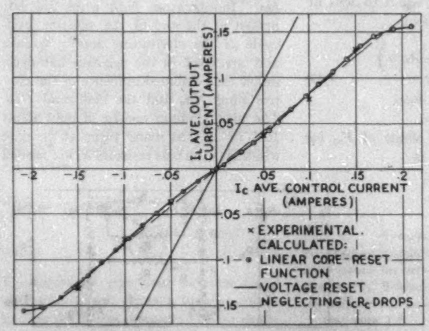

Fig. 11 (left). Control characteristic of half-wave bridge magnetic amplifier, cores 1A and 1B

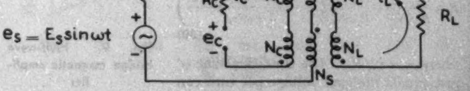
Fig. 12 (below). Fast-response even-harmonic magnetic amplifier



at α_1; the remaining volt-time integral of core B then appears across the load resistor R_L. During the interval when load current flows R_c/N_c^2 is in parallel with R_L/N_L^2 across the unsaturated core; therefore, R_c/N_c^2 must be large with respect to R_L/N_L^2 to avoid loading the output or drawing excessive currents in the control loop. Core B fires at α_2 and both cores remain saturated until the end of the half-cycle; R_s serves to limit the source current during this interval. In the succeeding half-cycle the process is repeated; e_s has changed sign, e_c has not and thus the sequence of firing of the cores is reversed, with the rectifier still blocking when both cores are unsaturated. Only positive signals are used. The output is pulsating direct current of which either the d-c component or the associated harmonics may be used by the load.

The cyclic average of load current I_L is given in terms of the difference $\Delta\phi$ of the two core fluxes at the first firing angle α_1 by

$$I_L = \frac{\omega N_L \Delta\phi - E_f(\alpha_2 - \alpha_1)}{\pi R_L} \tag{36}$$

where α_2 is the later firing angle. Since the control resistance is necessarily different from zero, $i_c R_c$ drops during reset may well be appreciable. The core voltages are large during reset so the linear core-reset function is applicable. Core A begins resetting at γ_1, core B at γ_2, and firings occur at α_1 and α_2 respectively. Here again, the calculation of $\Delta\phi$ requires the solution of the differential equations for the various intervals, calculation of the angles separating the various modes, and evaluation of the boundary conditions. The results of a numerical solution for a given amplifier are presented in Fig. 13. Quite close agreement is obtained using the linear core-reset function, but use of the 3-zone approximation of the core yields poor results. For very large values of control one core does not become saturated by the end of the half-cycle, and a double-valued region of the control characteristic results from a sort of "triggering" action. In practice, this range of control is avoided.

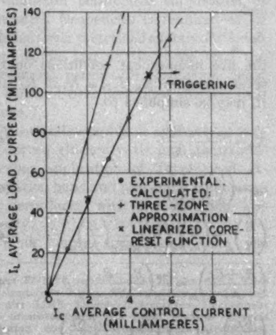


Fig. 13. Control characteristic of fast-response even-harmonic magnetic amplifier, cores 1A and 1B

Two-Core Self-Saturating Magnetic Amplifiers, Centertap, Full-Wave Bridge, and Doubler

The analysis of conventional 2-core self-saturating amplifiers, centertap, full-wave bridge, and doubler, Fig. 14, controlled from a constant current source, follows as an immediate extension of the analysis of the single-core half-wave amplifier with constant control current. In the 2-core amplifiers the average value of the load current may be easily evaluated in terms of the preset flux and gate voltage as the sum of the average gate currents which flow in alternate half-cycles. However, as one core resets, the value of the limiter voltage in its gate loop depends upon the gate current of the other core due to the common load voltage. Thus, operation of the 2-core amplifiers is not identical with that of two independent half-wave amplifiers, but the reset can be calculated with a proper evaluation of the limiter voltages in the gate loops. Results of such calculations are presented in Fig. 15 for a centertap amplifier; fair agreement is obtained with the experimental characteristic taken at the comparatively large value of R_c/N_c^2.

If the condition of constant control current is removed, an electromagnetic coupling between the cores through the control loop also becomes effective. At the beginning of a half-cycle, one core is in saturation and the other is at the preset flux level ϕ_p. In the prefiring interval the latter core absorbs the gate voltage until it saturates at α; meanwhile, the previously saturated core resets under the combined action of the control voltage E_c, the resistive drops $R_c i_c$ of the control circuit, and the voltage induced in the control circuit by the changing flux of the gating core. The core-reset function may be used in this interval to calculate ϕ and ϕ' in the resetting core.

After firing, the voltage of the gating core is nearly zero and may well be ignored at ordinary power frequencies for purposes of evaluating outputs. The voltage which does appear arises from the flux excursions, corresponding to the changing gate current, over the sloping "saturated" region of the loop. The flux level reached by the resetting core in the prefiring interval may not be altered greatly by the happenings in the postfiring interval, but the induced voltages may well be of the same order of magnitude as E_c and instantaneous control currents are dependent upon these voltages or, more precisely, on their difference. (Knowledge of the instantaneous control current is required for the ultimate evaluation of the average control current $I_c = E_c/R_c$ corresponding to the assumed ϕ_p and output.) As long as gate current continues to grow, the flux of the gating core increases, and the voltage induced in the control circuit remains in a direction to reset the other core, although the rate is much slower than before firing. But as the gate current recedes from its maximum value after the middle of the half-cycle, the induced voltage changes sign, opposing E_c, in a direction to return the reset core toward saturation even before the end of the half-cycle. Thus, for sinusoidal gate voltages, the instantaneous control current after firing cannot be evaluated under the use of the core-reset function, for the magnetic processes involve flux changes along the "top" and "bottom" and ascending branch of the minor loops where the

core-reset function is not applicable. However, for a square-wave gate voltage, the postfiring gate current would be essentially constant; the troublesome voltages induced in the control winding of the saturated core after firing would be eliminated, and the core-reset function could be used throughout the half-cycle to describe core reset.

Model Theory for Design of Analog Computers for Magnetic-Amplifier Systems

The availability of a core-reset function expressing dynamic core-reset in analytical form has a significance reaching beyond the analytical or numerical solution of the differential equations describing the various intervals of reset. Therefore the ability to formulate the system differential equations, properly accounting for the core behavior, opens the possibility of solution by analog techniques. In view of the nature of the physical system, which is described by differential equations, nonlinear, or perhaps linearized (using the linearized core-reset function) but with coefficients which vary from interval to interval, no simple analog with constant linear components is suitable. Electronic means could conceivably be used to synthesize an appropriate analog, but it appears more convenient to use magnetic cores as the basic components. The question is then reduced to one of formulating the rules of similitude governing the analogy between the system whose performance is to be predicted (the prototype) and the system on which measurements are to be performed (the model).

A comprehensive model theory aiming at predictions of behavior of a prototype on the basis of pertinent measurements performed on some different amplifier available for experimentation has been developed.[6] The rules presented, however, have been developed under the assumption of an existing affinity of the ϕ, F relationship (single- or double-valued) of the model and prototype, while the more recently acquired appreciation of dynamic phenomena (the influence of ϕ') was not considered. Analogies established under use of the more complete core-reset functions are, of course, much more exacting in the choice of the model cores, in the determination of the remaining components, and in the specification of the significant tests to be performed on the model. It appears likely that in some instances the problem of synthesis may be overdetermined and therefore impossible, but in other instances this analog approach may be fruitful.

As an example of the use of the model theory, consider the single-winding single-core half-wave amplifier, Fig. 1(A), controlled by a resistor R_s shunting the rectifier. In general, two physical systems are analogous only if they are described by the same set of differential equations with the same boundary conditions. To meet the restrictions on the core-reset function, the flux must reset from positive saturation; this restriction is met by the physical situation, and it will be convenient to measure the flux in terms of the difference from saturation: $\lambda=\phi-\phi_s$ and $\lambda'=\phi'$. The rectifier is assumed to act as an ideal switch. The mmf requirement of the core could be written in terms of the general core-reset function, but this would introduce the term $(-\lambda')^{a_3}$; a_3 is a dimensionless constant characteristic of the system, and one requirement will surely be that $a_{3m}=a_{3p}$, where subscripts m and p refer respectively to model and prototype. This condition may not necessarily imply an overdetermination of the conditions of analogy, but it may be difficult to meet practically in the selection of cores for the model. Thus it will be more convenient to develop rules of similitude under use of the linear core-reset function, rewritten in terms of λ as

$$F=b_0+b_1\phi_s+b_1\lambda+b_2\lambda' \tag{37}$$

where $0\geq\lambda\geq-2\phi_s$. To write the differential equations in dimensionless form the variable $\theta=\omega t$ is introduced; then $\lambda'=d\lambda/d\theta\times d\theta/dt=\omega d\lambda/d\theta$. Making these substitutions causes the differential equation of reset to become

$$\left[1+b_2\left(\frac{R_s+R_L}{N^2}\right)\right]\frac{\omega N}{E}\,\frac{d\lambda}{d\theta}+\frac{(R_s+R_L)/N^2}{E/N}\times$$
$$b_1\lambda+\frac{(R_s+R_L)/N^2}{E/N}\,(b_0+b_1\phi_s)=\sin\theta \tag{38}$$

In the gating half-cycle the differential equation is

$$\frac{\omega N}{E}\,\frac{d\lambda}{d\theta}+\frac{R_L/N^2}{E/N}\,F=\sin\theta \tag{39}$$

since the core-reset function does not apply for ascending fluxes, no substitution is made here for F. Relating fluxes and mmf of model and prototype as follows:

$$\lambda_p=K_\phi\lambda_m \tag{40}$$

and

$$F_p=K_fF_m \tag{41}$$

the five independent conditions on the seven variables: K_ϕ, K_f, ω, N, E, R_L, and R_s may be simplified to

$$K_\phi=\frac{(\phi_s+b_0/b_1)_p}{(\phi_s+b_0/b_1)_m} \tag{42}$$

$$\omega_m=\left(\frac{b_2}{b_1}\right)_p\left(\frac{b_1}{b_2}\right)_m\omega_p \tag{43}$$

$$\left(\frac{E}{N}\right)_m=\left(\frac{b_2}{b_1}\right)_p\left(\frac{b_1}{b_2}\right)_m\frac{1}{K_\phi}\left(\frac{E}{N}\right)_p \tag{44}$$

$$\left(\frac{R_s+R_L}{N^2}\right)_m=\frac{b_{2p}}{b_{2m}}\left(\frac{R_s+R_L}{N^2}\right)_p \tag{45}$$

$$\left(\frac{R_L}{N^2}\right)_m=\left(\frac{b_2}{b_1}\right)_p\left(\frac{b_1}{b_2}\right)_m\frac{K_f}{K_\phi}\left(\frac{R_L}{N^2}\right)_p \tag{46}$$

Two further relationships between E, N, R_S, R_L, and K_f may be imposed;

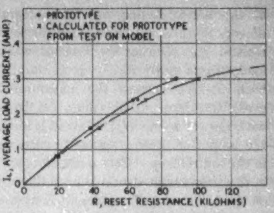

Fig. 16. Control characteristic of prototype and prediction from model

ω_m and K_a are fixed by the parameters of the prototype and the properties of the core used for the model.

An experimental check of this analysis was made with the use of cores and circuit parameters as listed in Table II. In Fig. 16 the control characteristic calculated for the prototype from measurements on the model is compared with the actual experimental data for the prototype. The agreement is fairly good, the error in predicted values being less than 10%. Sources of error aside from the use of the linearized core-reset function may be in the rectifier imperfections (leakage and forward drop), and the nonzero slope of the F, ϕ relation in the saturated region.

This is but one example of the solution of magnetic-amplifier problems by analog methods. No further attempt will be made here to investigate the ramifications of the model theory or applications to other circuits or systems, but it is suggested that the improved representation and understanding of dynamic core behavior opens the field for devising and performing pertinent experimentation on analogous circuits to determine steady-state and transient performance of magnetic amplifiers. There may be limitations as to the circuits which may be treated in this way, but it is encouraging to note that for the foregoing example the analogous system was not overdetermined and that there was some freedom of choice in selecting the parameters of the model.

Summary

The core-reset functions which were developed in Part I to better express core behavior under dynamic conditions of changing flux have been used here in several examples to calculate the steady-state magnetic-amplifier performance with quite good accuracy. Although a thorough analysis becomes somewhat involved, the computational work may be readily performed with digital computers. Moreover, the core-reset functions lead to some results of general applicability in magnetic-amplifier analysis and design, and the understanding of simple reset problems and the approximate solution of more complex problems are both aided by the improved description of core behavior. The possible use of magnetic cores as analog computer components for the calculation of steady-state and transient performance of magnetic-amplifier systems is suggested as a potent analytical tool to be developed further.

Insertion Loss Filter Design Applied to Transistorized Carrier System

T. WINKLER
NONMEMBER AIEE

IN MANY filter design problems, the minimum permissible suppression of unwanted frequencies is required to be constant over prescribed effective attenuation bands, and at the same time the maximum permissible distortion must be constant over prescribed effective pass bands.

Most design problems of this type may be solved efficiently through the simultaneous application of Tchebycheff attenuation band and pass-band parameters in accordance with the insertion loss theory.

While more complicated than the image-parameter theory, which has dominated practical filter design almost exclusively for many years, this theory sometimes permits the realization of greater network economy exhibiting superior and better controlled electrical characteristics with no increase in cost. Its general problem is to find a reactance 4-pole yielding prescribed insertion loss versus frequency function when inserted between prescribed resistance terminations.

Although a general application of the insertion loss method is theoretically possible, complicated numerical computations requiring a very high accuracy originally limited its practical usefulness. The introduction, however, of computing equipment, that has become in recent years a steady companion of a modern electronics designer, and a growing tendency toward miniaturization (especially after the invention of the transistor) combined with performance requirements, not easily satisfied with image-parameter designs, have led to an extensive use of the insertion loss theory in recent years.

Basic Theory

The use of Tchebycheff parameters in network theory was first introduced by Cauer,[1,2] then explored by Piloty[3] and Darlington.[4] It was Darlington's work that provided the basis for the design described in this paper.

Darlington also originated the "reference filter" design, based on Tchebycheff's pass-band parameters, which requires the frequencies of infinite loss to be known.

The starting point of the design procedure is the search for an insertion power ratio of an equivalent normalized low-pass filter. This applies to filters other

$j\frac{\Omega z_n}{a_{2n}}$
$\frac{1}{j\Omega a_{2n}}$

Fig. 2. Impedance branches of a mid-series low-pass ladder

than low-pass filters. In the remaining case the actual filter takes the place of the equivalent structure, except for normalization of its impedance and frequency scale.

The insertion loss versus frequency characteristic of the normalized low-pass filter is shown in Fig. 1, in which η represents the number of "sections." Its value depends on α_p, α_s and k. Since η must be an integer, one of these variables may have to be modified.

Darlington's corresponding power ratio, required for a symmetrical low-pass filter, takes the form

$$\epsilon^{2\alpha}=1+\left[S_0\frac{\Omega(\Omega^2-\Omega_1^2)\ldots(\Omega^2-\Omega_n^2)}{(1-\Omega_1^2\Omega^2)\ldots(1-\Omega_n^2\Omega^2)}\right]^2 \quad (1)$$

where

$$\Omega=\frac{\omega}{\sqrt{\omega_1\omega_2}} \quad (2)$$

with ω_1 and ω_2 being the values of ω at cutoff frequency and the limit of the effective attenuation band,

$$\Omega_\sigma=\sqrt{\kappa}\ \mathrm{sn}\left(\frac{2\sigma K}{2\eta+1}, \kappa\right) \qquad \sigma=1, \ldots, \eta \quad (3)$$

where

sn = elliptic sine

$\kappa=\omega_1/\omega_2$ = modulus

$K=\int_0^{90^\circ}\frac{d\varphi}{\sqrt{1-\kappa\sin^2\varphi}}$ = "complete elliptic" integral of the first kind

S_0 = function of α_p in Fig. 1

After the roots of equation 1 have been determined, two ways of realization are available. The first is by the corresponding complex insertion voltage ratio

$$\frac{V_{20}}{V_2}=\frac{A+pB}{P} \quad (4)$$

where

V_{20} = complex voltage received before insertion of the network

V_2 = complex voltage received after insertion of the network

$p=j\Omega$

and A, B, and P are even polynomials in p, with real coefficients that may be determined by making use of the definition

$$\epsilon^{2\alpha}=\left|\frac{V_{20}}{V_2}\right|^2 \quad (5)$$

In addition to polynomials A and B, the polynomial

$$B'=-\Pi_\sigma(p^2+\Omega_\sigma^2) \quad (6)$$

is evaluated.

A, B, and B' permit the determination of the short-circuit driving point impedance of the normalized low-pass structure

$$Z_{s1}=\frac{p(B-B')}{A} \quad (7)$$

The continued fraction expansion of

$$F=\frac{Z_{s1}}{p}=a_1+\cfrac{1}{\cfrac{a_2}{z_1-z}+\cfrac{1}{a_3+\ldots}} \quad (8)$$

with

$$z=-\frac{1}{p^2}=\frac{1}{\Omega^2}$$

$$z_v=\Omega_v^2 \qquad v=1, \ldots, \eta \quad (9)$$

supplies the ladder-network coefficients $a_1, \ldots, a_{2n+1}$, whose meaning is explained in Fig. 2. The second realization method is by using the insertion power ratio expression

$$\epsilon^{2\alpha}=1-\left(\frac{pB'}{P}\right)^2 \quad (10)$$

The quantity

$$P+pB'=(P_1+pB_1)(P_2-pB_2) \quad (11)$$

could be determined by associating all roots having negative real parts with (P_1+pB_1). With the use of the identities

$$Z_A=R\frac{pB_2}{P_2},\ Z_B=R\frac{P_1}{pB_1} \quad (12)$$

one lattice, producing the prescribed power ratio, could be built (Fig. 3) and then transferred into an equivalent ladder of the kind shown in Fig. 2.

It turns out that there are four corresponding lattices. The one chosen conforms with the already available table of special design formulas.[4]

Although the methods described apply to symmetrical networks only, the first could be modified easily to permit the realization of inverse impedance networks.

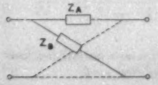

Fig. 3. The lattice configuration

The second method has been used in the design described in the following.

Design Objectives and Procedures

The attenuation requirements for the *561* subscriber carrier channel band-pass filters are given in Fig. 4.

Ten carrier frequencies have been assigned between 15 and 123 kc (kilocycles per second) in equal steps of 12 kc. The filters should meet the requirements shown in Fig. 4 when all ten are operated in parallel.

It has been mentioned that the theory and procedures of low-pass filter design also include the cases of band-pass filters.

Where the band-pass insertion loss specification has complete geometric symmetry about some mid-band frequency, the well-known band-pass/low-pass transformation is applicable (see chap. 10 of reference 5). After designing a low-pass filter to this transformed specification the band-pass filter is arrived at by a simple frequency transformation of the network elements themselves, in which inductances and capacitances are replaced by series- and parallel-resonant circuits respectively.

Although the foregoing requirements do not contain the necessary symmetry, this method of design, producing higher-than-required attenuation in the lower frequency transition region, is less complicated and supplies more design flexibility than any known design procedure applicable to structures with other than geometric symmetrical attenuation.

Darlington[4] and Boothroyd[6] have independent ways of solving such problems; the former's is based on Norton's impedance transformation and latter's on low-pass filter design with different attenuations for positive and negative frequencies. The author's treatment of this problem with the aid of an electronic computer and application of a conformal transformation is scheduled to be published.

The maximum pass-band loss of 1.8 db

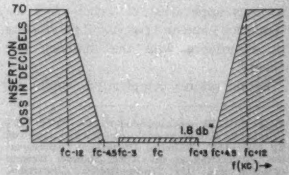

Fig. 4. Insertion loss specification

*The insertion loss between f_c-3 and f_c+3 should be flat within 25 db

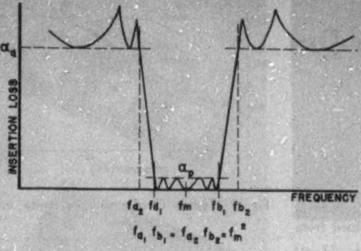

Fig. 5. Form of filter characteristic meeting the design specifications

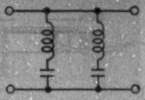

Fig. 7. Alternative shunt branch configuration

(decibels) required a design on a nondissipative basis. The effect, however, of the parasitic dissipation, which must be present in an actual reactance network, cannot be neglected and its effect on the theoretical attenuation curve should be predicted and accounted for. The form of insertion loss characteristic of a band-pass filter described in the foregoing is shown in Fig. 5.

Should the parasitic dissipation be neglected, all constants, but one, required to establish the corresponding low-pass power ratio (equation 1) are as follows:

$$k=\frac{f_{b1}-f_{a1}}{f_{b2}-f_{a2}}$$

$$\alpha_p=0.3\times 0.11513=0.034539 \text{ neper}$$

$$\alpha_a \geqq 70 \text{ db} \qquad (13)$$

In this case the frequencies f_{a1}, f_{b1}, and f_{b2} correspond to f_{c-3}, f_{c+3}, and f_{c+12} in Fig. 4 respectively; $f_{a2}=f_{a1}\,f_{b1}/f_{b2}$ then falls into the transition region.

The missing constant required in equation 3 is η, which is the same for both filters provided sections of the 6-element type of configuration are considered in the band-pass case. Its minimum value is determined from its relation with α_p, α_a, and k, given by the equation

$$\alpha_a=[10\log_{10}(e^{2\alpha_p}-1)-10(2\eta+1)\log_{10} q-12.04]\text{db} \qquad (14)$$

in which $\log_{10}(q)$ is a quantity which is tabulated against $\sin^{-1}k$ in elliptic function tables (see page 49 of reference 7).

Equation 14 is an approximation. It follows from the equation

$$e^{2\alpha_a}=1+\frac{e^{2\alpha_p}-1}{\kappa_1^2}$$

which for large α_a and small α_p reduces to

$$e^{2\alpha_a}\approx\frac{e^{2\alpha_p}-1}{\kappa_1^2}\approx\frac{e^{2\alpha_p}-1}{16q_1\dfrac{1+4q_1^2}{1+8q_1+24q_1^2}}\approx\frac{e^{2\alpha_p}-1}{16q_1}$$

and with use of the identity $q_1=q^{2\eta+1}$ assumes the required form

$$e^{2\alpha_a}\approx\frac{e^{2\alpha_p}-1}{16q^{2\eta+1}}$$

Using equation 14 and remembering than η is the number of ladder sections, a table of values for various k's, with $\eta=1,2,3,\ldots$ as a parameter, could be computed. This has been done for the lowest frequency network with the following results:

η	α_a, db
1	41.98
2	84.63
3	129.29

with

$$k=\frac{6}{27-\dfrac{12\times 18}{27}}=0.315789 \qquad (15)$$

and

$$\alpha_p=0.3 \text{ db}$$

Use of two sections seemed to be required. The excess of attenuation, however, had to be exchanged for smaller α_p and larger k, to provide enough margin for the effect of parasitic dissipation, manufacturing variations, and temperature effect.

After choosing $\alpha_p=0.1$ db and $\sin^{-1}k=22$ degrees, equation 14 establishes α_a to be 72.8 db.

The next step is the evaluation of bandwidth $D=f_{b1}-f_{a1}$, corresponding to k. As a result, the required equation takes the form

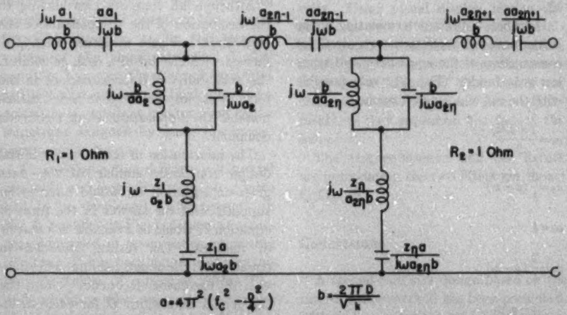
$$D_{\max}=\left[\frac{2(f_c+12)}{k}-\sqrt{\left[\frac{2(f_c+12)}{k}\right]^2-96(f_c+6)}\right]\text{kc} \qquad (16)$$

with f_c being the carrier frequency called for in Fig. 4, expressed in kc.

Equation 16 reveals another very important aspect of this procedure: with the sharpness of cutoff, expressed in the value of k, being constant, the theoretical maximum bandwidth $D_{\max}$ will increase when the carrier frequency f_c increases. The values of $D_{\max}$ corresponding to the prescribed f_c's have been computed as:

f_c, Kc	$D_{\max}$, Kc
15	7.179
27	7.760
39	8.061
51	8.244
63	8.368
75	8.456
87	8.523
99	8.576
111	8.618
123	8.652 (17)

This behavior of $D_{\max}$ permitted the use of a single equivalent low-pass filter,



$j\omega\frac{a_1}{b}$
$\frac{aa_1}{j\omega b}$
$j\omega\frac{a_{2\eta-1}}{b}$
$\frac{aa_{2\eta-1}}{j\omega b}$
$j\omega\frac{a_{2\eta+1}}{b}$
$\frac{aa_{2\eta+1}}{j\omega b}$
$j\omega\frac{b}{aa_2}$
$\frac{b}{j\omega a_2}$
$j\omega\frac{b}{aa_{2\eta}}$
$\frac{b}{j\omega a_{2\eta}}$
$R_1=1$ Ohm
$R_2=1$ Ohm
$j\omega\frac{z_1}{a_2 b}$
$j\omega\frac{z_\eta}{a_{2\eta} b}$
$\frac{z_1 a}{j\omega a_2 b}$
$\frac{z_\eta a}{j\omega a_{2\eta} b}$
$a=4\pi^2\left(f_c^2-\frac{D^2}{4}\right)$
$b=\frac{2\pi D}{\sqrt{k}}$

whose characteristic is plotted against the normalized frequency in Fig. 1.

The required design constants have been chosen to be

$$k=0.37461$$

$$\eta=2$$

$$\alpha_p=0.1 \text{ db} \tag{18}$$

Using the approximation

$$p_0=\frac{\sqrt{k}\,\mathrm{sn}\,(u',\sqrt{1-k^2})}{\mathrm{cn}\,(u',\sqrt{1-k^2})} \tag{19}$$

where

$$u'=\frac{2K}{\pi(2\eta+1)}\sinh^{-1}\frac{1}{\sqrt{\epsilon^{2\alpha_p}-1}}$$

the evaluation of the real root of the power ratio equation 1 was possible. The error in p_0 will produce only a small change in the original value of α_p and a respective small change in α_a in accordance with equation 14.

The expression

$$\mathrm{sn}\,(u',\sqrt{1-k^2})=\mathrm{sn}\,(rK',k') \tag{20}$$

with

$$r=u'/K'$$

$$k'=\sqrt{1-k^2}$$

K' = complete integral corresponding to modulus k'

was evaluated using the approximation[8]

$$\mathrm{sn}\,(rK',k')=\frac{1}{\sqrt{k'}}\frac{(1-t^r-t^{2-r}+t^{2+2r}+\dots)}{(1+t^r+t^{2-r}+t^{2+2r}+\dots)} \tag{21}$$

where

$$t=\frac{1}{2}\frac{1-\sqrt{k'}}{1+\sqrt{k'}}+\dots$$

The values of K are tabulated against $\sin^{-1}k$ in elliptic function tables (see page 85 of reference 7) and in addition there are the following rapidly convergent series:

$k^2 \ll 1$:

$$K=\frac{\pi}{2}\left(1+2\Delta+9\Delta^2+50\Delta^3+\frac{1{,}225}{4}\Delta^4+\dots\right)$$

with

$$\Delta=k^2/8$$

$k^2 \approx 1$:

$$K=\Lambda+\frac{\Lambda-1}{4}k'^2+\frac{9}{64}\left(\Lambda-\frac{7}{6}\right)k'^4+\frac{25}{256}\left(\Lambda-\frac{37}{30}\right)k'^6+\dots$$

with

$$k'=\sqrt{1-k^2}$$

$$\Lambda=\ln(4/k')$$

After sn (u',k') has been determined, the value of cn (u',k') is obtained from the equation

$$\mathrm{sn}^2+\mathrm{cn}^2=1 \tag{22}$$

Using equations 19 through 21 the positive real root is found to be

$$p_0=0.34627351 \tag{23}$$

The complex roots are then evaluated using the approximation equation 21 and the formula

$$p_\sigma=\frac{(-1)^\sigma p_0 cd_\sigma \pm jW\Omega_\sigma}{1+p_0^2\Omega_\sigma^2}=(-1)^\sigma{}_{\gamma\sigma}\pm j\beta_\sigma,\quad \sigma=1,2 \tag{24}$$

where

$$W=\sqrt{(1+kp_0^2)\left(1+\frac{1}{k}p_0^2\right)}$$

$$cd_\sigma=\sqrt{(1-\mathrm{sn}_\sigma^2)(1-k^2\mathrm{sn}_\sigma^2)}$$

$$\Omega_\sigma=\sqrt{k}\,\mathrm{sn}_\sigma$$

$$\mathrm{sn}_\sigma=\mathrm{sn}\left(\frac{2\sigma}{5}K,k\right)$$

Their values are

$$p_1=-0.26526433\pm j0.42532405$$

$$p_2=0.09338782\pm j0.65868852 \tag{25}$$

After the roots of the power ratio have been computed, the impedance arms of the corresponding lattice are easily available with the aid of equations 11 and 12.

However, a direct determination of the ladder-network coefficients, required for construction of the equivalent mid-series low-pass ladder (Fig. 2), was possible with the aid of a set of formulas

$$a_1=\frac{1-\rho_1^2z_1}{2\gamma_1}$$

$$a_2=\frac{2}{\delta}(\psi-z_1)$$

$$a_3=\delta$$

$$a_4=\frac{2}{\delta}(\psi-z_2)$$

$$a_5=\frac{1-\rho_1^2z_2}{2\gamma_1} \tag{26}$$

where

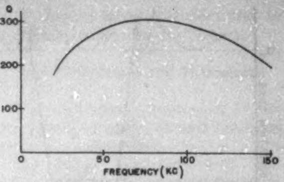

Fig. 9. Typical Q of a variable ferrite inductor

$$\delta=\frac{\rho_1^2}{\gamma_1}\left(\psi-\frac{z_1+z_2}{2}\right)$$

$$\psi=\frac{p_0+2_{\gamma_2}}{p_0\rho_2^2}$$

$$\rho_r^2=\gamma_r^2+\beta_r^2$$

These formulas were computed using equations 11 and 12 and Darlington's Table II.[4]

The coefficients could also be evaluated from equations 8 and 9 by replacing Z_{s1} with $Z_{01}=1/2(Z_A+Z_B)$, as

$$F=\frac{Z_{01}}{p}=\frac{1}{2}\left(\frac{Z_A}{p}+\frac{Z_B}{p}\right)=F_1(z)=\frac{1}{2}(F_{1A}+F_{1B})$$

and by using the formulas given in the Appendix.

The coefficient $a_{2\eta+1}$, corresponding to the inductance forming the last series arm, may then be obtained from the formulas for a_1, by replacing z_1 with z_η.

By combining equation 9, 24, and 26 the numerical values are determined as:

$$z_1=0.13544096$$
$$z_2=0.34077093$$
$$a_1=1.82076559$$
$$a_2=2.17832867$$
$$a_3=3.06903102$$
$$a_4=2.04452098$$
$$a_5=1.72351847 \tag{27}$$

Although all computations leading to the evaluation of the components of the equivalent low-pass structure were performed with the aid of a desk calculator, the availability of approximations in the form of rapidly convergent series makes possible the application of an electronic computer.

The information in terms of the initial design constants, similar to the ones given in equation 18, would have to be supplied, and the answer in the form of equation 27 would be available in a matter of minutes. The results obtained in equation 27, the design constant k in equation 18, the carrier frequency f_c, and the theoretical bandwidth D for each structure are required for the evaluation of components of the respective band-pass filter, using the impedance formulas given

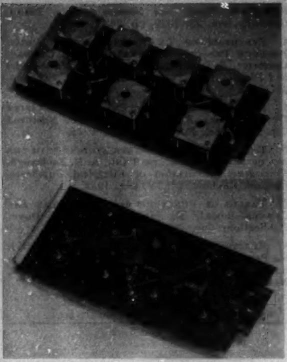

Fig. 10. Typical filter assembly

in Fig. 6. The shunt branches are replaced by configurations of the type shown in Fig. 7.

The impedance level was not originally defined because of the flexibility of the assigned transformation ratio of the mutual repeating coil; therefore, the terminations R_1 and R_2, representing the generator internal resistance and the load respectively, were chosen to be 300 ohms.

At this level the coils in all ten filters assumed values permitting the resistance-reactance ratios $d_L = 1/Q_L$ to be less than 1/200 within the respective pass bands.

At the same time, the required capacitors, with the exception of very few in lower frequency units, were in the mica range.

Physical Realization

The distinguishing feature of the insertion loss theory is the use of an exactly prescribed insertion loss versus frequency function to fix the element values of the final network. Unfortunately, however, the effect of variations in these elements on the final filter characteristic is somehow greater than in the structures designed by using the image-parameter technique.

To overcome this deficiency a special assembly and new adjustment procedures had to be developed. The network in Fig. 6, modified in Fig. 7, presents a structure composed of seven series-resonating circuits. It has been found that controlling the values of capacities within 1%, and adjusting the resonant frequencies of each circuit to their nominal values, would produce adequate results.

While 1% capacitors were easily available, variable inductors were required to make the frequency adjustments possible and practical. An inductor of this kind is shown in Fig. 8.

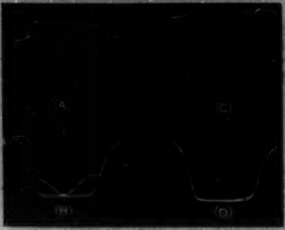

Fig. 11. Loss characteristic of the standard filter and a filter under test

A, B—Attenuation bands and pass band before adjustment
C, D—After adjustment

Two ferrite pot core halves, with center posts separated by an air gap, a ferrite slug whose position within the air gap may be adjusted with a screw driver, and a plastic bobbin are the basic elements of the assembly.

The dimensions were chosen to make possible manufacture of all inductors used in these filters with only two standard air gaps. While their inductance range was somewhere around ±10%, requiring a different number of turns for most of the specified values, the Q and the temperature coefficient of each coil met the requirements with considerable safety margin. A typical Q versus frequency performance is shown in Fig. 9 and a filter assembly in Fig. 10.

Use of adjustable inductors also offered great manufacturing advantages. Only one filter of a kind had to be carefully adjusted in accordance with the design results. Using visual display testing circuits, the rest of the units could be almost completely adjusted on a comparison basis. Fig. 11 shows the loss characteristics of the "standard" filter and of one filter under test before and after adjustments, as they appear on the face of the scope.

The test equipment and the fixture accommodating the two filters are shown in Fig. 12.

Conclusions

A special case of a design based on the insertion loss method has been presented. Although a complete set of formulas is given for a design of symmetrical band-pass filters with two 6-element sections, design of structures containing a different number of sections η (corresponding to a specific set of requirements) may be performed by letting σ in equation 24 be equal to 1,2, ... η, and computing the respective set of formulas, corresponding to equation 26. Useful information concerning the evaluation of coefficients from the continued fraction expansion, equation 8, that would be required for designs based on the computation of the respective open- or short-circuit impedances is given in the Appendix.

Fig. 12. Visual display test equipment

The visual display testing circuits, employing standard networks, have been used satisfactorily for many years for various applications, but their use for adjustment and testing of synthesized 4-poles appears to be almost a necessity.

Appendix

Let Z denote any open- or short-circuit impedance of the 4-pole reactance. By dividing the impedance function by $p = j\Omega$, a new function is obtained

$$F = \frac{Z(p)}{p} = F(p^2)$$

Replacing p^2 with a new variable

$$s = -\frac{1}{p^2}$$

produces

$$F_1 = F_1\left(-\frac{1}{s}\right) = F_1(s) = \frac{C_1(s)}{D_1(s)}$$

The ladder-network coefficients, corresponding to Fig. 2, are now available through the use of the following formulas:

$$a_1 = F_1(s_1) = \frac{C_1(s)}{D_1(s)}$$

$$a_2 = -\frac{D_1(s_1)}{C_2(s_1)}$$

$$a_3 = \frac{C_2(s_2)}{D_2(s_2)}$$

$$a_4 = -\frac{D_2(s_2)}{C_3(s_2)}$$

$$C_2(s) = \frac{C_1(s) - a_1 D_1(s)}{s - s_1}$$

$$D_2(s) = \frac{D_1(s) + a_2 C_2(s)}{s - s_1}$$

$$C_3(s) = \frac{C_2(s) - a_3 D_2(s)}{s - s_2}$$

The evaluation of the coefficients continues until the last one, corresponding to the impedance $Z(p)$, is available. The respective functions C and D required for its evaluation, then are constants.

Proposed Standards for Core Test Methods for Toroidal Magnetic Amplifier Cores

AIEE COMMITTEE REPORT

ONE OF THE major problems in the production of magnetic amplifiers is reproducibility. It is essential that reactor cores of magnetic amplifiers be tested and selected prior to winding if good quality control is to be maintained. There have been many approaches to the problem and each company has its own test circuit. Realizing that it would be advantageous to both the core vendors and the users to standardize on core test methods, the Magnetic Amplifier Materials Subcommittee formed the Working Group on Core Matching and Grading to establish standard test circuits. This paper constitutes a summary of the Working Group's activities over a 2-year period and sets forth recommendations for two standard core test circuits for toroidal cores.

To survey the field, questionnaires were sent to 46 companies who are active in the magnetic-amplifier field. The information received from the 18 companies that answered formed the pool of informaton from which the standard test circuits were determined.

The information was evaluated in the light of the following:

1. Reproducibility of results.
2. Correlation of test data with amplifier performance.
3. Simplicity of circuitry.
4. The number of companies employing each of the submitted test circuits.

All of the proposed test circuits, including the circuits presented in this paper, excite the core in such a manner that the resulting flux excursions as a function of time differ from the excursions that take place in actual magnetic-amplifier operation. From this point of view the circuits are not ideal. The departure, however, is acceptable in view of the fact that correlation of test results with amplifier performance is acceptable.

Of the seven types of test circuits proposed, two were selected. They are the constant-current-flux-reset (CCFR) test and the sine-current-excitation (SCE) test. It was impossible to eliminate either one in preference to the other since both are widely used and neither presents outstanding advantages over the other. The operation of both of these circuits has been well described in previous literature.[1–3] The purpose of this paper is to establish conditions of measurement so that test results may be reproduced from one test installation to the next.

The SCE test measures magnetic parameters while the flux is traversing a major dynamic hysteresis loop. The CCFR test, on the other hand, simulates the operation of a single core half-wave magnetic amplifier. Measurements are made while the flux traverses minor dynamic hysteresis loops.

In both test methods magnetic properties are obtained by measuring electrical quantities. The test equipment is calibrated in magnetic units, since core properties are the quantities of interest.

Since the two test methods excite the core in different ways, one should not expect to obtain the same quantitative results. Only in the measuring of peak induction (B_m) and peak induction minus residual induction ($B_m - B_r$) are the test conditions identical in the two circuits.

CCFR Core Test Method

A1.0. GENERAL DESCRIPTION

A1.1. The CCFR core test method provides a means for measurement of core magnetic properties under operative conditions which approximate conditions in several different types of self-saturating magnetic-amplifier circuits. The test employs an excitation current consisting of half-wave sine current pulse of sufficient magnitude to drive the core flux into positive saturation. A d-c demagnetizing force of adjustable magnitude is applied to the core so as to reset flux away from positive saturation during the intervals between pulses of excitation current. The resultant cyclic flux change is measured by means of a sensitive flux volt-

meter connected to a separate pickup winding on the core. A low number of excitation, control, and pickup turns are used to facilitate rapid jigging of cores.

A1.2. Test data are obtained by measuring values of induced pickup voltage as a function of the applied demagnetizing control ampere-turns under conditions of half-wave sinusoidal excitation current of constant magnitude. For some purposes these data may best be presented in the form of a curve. For general production, core grading and matching data are obtained only at particular standardized test points. These standard test points are selected as shown in Fig. 1 to determine the bias point H_0 and the gain G in the linear region of the curve. Also, the difference between peak induction and residual induction ($B_m - B_r$) is measured using zero control ampere-turns.

A1.3. The measurement of peak flux density is made by employing full-wave SCE. This measurement can best be made by switching to a full-wave sine current supply instead of a half-wave supply, and using zero control ampere-turns.

A2.0. TEST CIRCUIT

A2.1. A simplified schematic diagram of the test circuit is shown in Fig. 2. The circuit consists of five major blocks: full-wave sine current supply, half-wave sine current supply, d-c control current supply, test jig, and flux voltmeter. The requirements on these various units are given in the following paragraph.

A2.2. A sinusoidal and half-wave sinusoidal current supply shall be provided. These may be separate current supplies, or may be obtained from a common source by suitable switching and rectifying means.

A2.3. Plug-in type test jig:

A2.3.1. A single or double (differential) plug-in type of test jig shall be used. A single test jig shall have a plug-in connector having an excitation winding, a pickup winding, and a control winding.

A2.3.2. If a double or differential type of test jig is employed, the excitation windings of the two plug-in connectors shall have equal numbers of turns and shall be connected in series. The pickup windings of the two plug-in connectors shall have equal numbers of turns, and shall be connected in series opposition. Also, the control windings shall have equal turns and shall be connected in series with the same polarity connections as the excitation windings.

A2.3.3. Provision for cancellation of voltage pickup due to air induction linking the excitation winding with the pickup winding shall be made, if necessary.

A2.4. Flux voltmeter: Either an averaging instrument sensitive to total flux change or an integrating flux voltmeter shall be used to meter the core output voltage.

A3.0. EXCITATION AND CONTROL REQUIREMENTS

A3.1. Voltage source:

A3.1.1. The voltage of the excitation source shall be sinusoidal, with a harmonic content of less than 10% and shall have an rms amplitude greater than 100 times the half-cycle average value of voltage induced in the excitation winding.

A3.1.2. The frequency of the voltage source shall be known within 1%, and if not known within these limits, it shall be measured to an accuracy of 1%.

A3.1.3. Standard test frequencies of 60, 400 or 1,600 cps (cycles per second) may be used within the frequency limitations of the test circuitry and instrumentation. The tolerance on any standard test frequency used shall be ±5%.

A3.2. Excitation windings:

A3.2.1. The excitation winding on the test jig shall consist of a single turn, wherever possible, but shall not exceed six turns.

A3.2.2 All excitation windings shall be kept in a fixed position in relation to the pickup windings, and to nearby circuits and equipment, during testing.

A3.2.3. When differential core matching is desired, two identical excitation windings shall be used, connected in series. Geometric symmetry of the excitation windings in relation to each other shall be maintained.

A3.3. Excitation current:

A3.3.1. The half-wave excitation current shall be essentially sinusoidal. For values of current from 5% to 25% of peak excitation current, the time interval between an instantaneous value of current on the descending portion of the current waveform to an equal value of current on the ascending portion of the next half-cycle of current shall be within ±3% of the corresponding time interval for a perfect half-wave sinusoid.

A3.3.2. During the interval between pulses when the excitation current is nominally zero, the maximum instantaneous current occurring because of rectifier leakage or other cause is to be less than 0.1% of the peak value of excitation current during a pulse.

A3.3.3. The full-wave excitation current shall contain less than 25% harmonic distortion.

A3.3.4. The peak value of excitation current shall be measured to an accuracy of ±2%.

A3.4. Peak magnetizing force:

A3.4.1. The following peak magnetizing force shall be applied for the commonly used core materials. The value of peak magnetizing force applies to materials whose tape thickness is 6 mils or less, when tested at 400 cps or below; or whose tape thickness is from 6 to 14 mils when tested at 60 cps.

Material	Peak Magnetizing Force When Measuring H_0, H_1, H_2, Oersteds	Peak Magnetizing Force When Measuring B_m and (B_m-B_r), Oersteds
3% silicon iron (oriented)	6.0	3.0
50% nickel-iron (oriented)	2.0	1.0
79% nickel-iron	1.0	0.5
Supermalloy	0.5	0.25

where

$H_m=0.4\pi N_e I_m/l$ oersteds
H_m = peak magnetizing force
N_e = number of excitation winding turns
I_m = peak value of excitation current
l = mean core length, cm (centimeters)

A3.4.2. When conditions other than those covered in paragraph *A3.4.1* are employed, the nearest larger value of peak magnetizing force shall be selected, rounded off to one significant figure, i.e., twice the value of the highest sine current coercive force to be expected.

A3.5. D-c control current:

A3.5.1. The rms ripple of the control current shall not exceed 0.25%.

A3.5.2. Control current corresponding to H_0, H_1, and H_2 (Fig. 1) shall be measured to within ±1%.

A3.5.3. Changes in control current corresponding to ΔH(Fig. 1) shall be measured to ±2%.

A4.0. MEASUREMENT AND REQUIREMENTS

A4.1. Pickup windings:

A4.1.1. The pickup winding on the test jig provides an induced voltage for measuring the dynamic hysteresis loop characteristics of the core under test. The pickup winding shall consist of a single turn when possible, but may have any convenient number of turns.

A4.1.2. All pickup turns shall be maintained in a fixed position relative to the excitation windings and to other nearby equipment during core testing.

A4.1.3. Whenever possible, the pickup windings shall be so arranged in relation to the excitation windings that the inductive and capacitive coupling between them is minimized so that, with no core in the jig, no induced voltage appears on the output of the pickup windings with maximum current flowingat the test frequency in the excitation winding.

A4.1.4. If the average induced voltage from the pickup winding under the conditions of paragraph *A4.1.3*, due to mutual coupling between the excitation and the pickup windings, exceeds 0.5% of the average output voltage corresponding to the peak magnetizing force, this mutual inductive coupling between the excitation winding and the pickup winding shall be adjusted so as to reduce the induced voltage to less than 0.5%. If necessary, an air core bucking transformer shall be used for this purpose.

A4.1.5. Where differential core matching is desired, two identical pickup windings shall be used, connected in series opposition. Geometric symmetry of the pickup windings in relation to each other, and to the excitation windings, shall be maintained.

A4.1.6. The average output voltage of the differential jig of paragraph *A4.1.5*, with no cores in the windings and with maximum excitation current flowing at the test frequency, shall be less than 0.5% of the average voltage obtained with only one core in the differential test windings. The mutual inductive coupling between one of the excitation and pickup windings of the differential test jig shall be adjusted to reduce the induced voltage to less than 0.5%.

A4.2. Flux voltmeter input impedance:

A4.2.1. The average sensitive or integrating flux voltmeter shall have negligible loading effect on the core. Its input impedance must be such that

$$R>2\pi f N_s \frac{2A}{l} G\times 10^{-8}$$

where

R = meter input impedance
N_s = pickup winding turns
A = core cross-section area, cm^2
l = mean length of magnetic path of the core, cm
f = test frequency, cps
$G=(\Delta B_2-\Delta B_1)/\Delta H$, gausses per oersted (see Fig. 1)

A4.2.2. The average sensitive or integrating flux voltmeter shall have an accuracy of ±1% of reading.

A4.3. Standard test points:

A4.3.1. Data shall be taken at the following test points:

a. B_m at H_m specified in paragraph *A3.4.1*.

b. B_m-B_r, at control $H=0$.

c H_0 at specified ΔB_0 (paragraph *A4.3.2*).

d. H_1 at specified ΔB_1 (paragraph *A4.3.2*).

e. H_2 at specified ΔB_2 (paragraph *A4.3.2*).

A4.3.2. ΔB_1, ΔB_0, and ΔB_2 as independent variables should be adjusted as follows:

Material	ΔB, Kilogausses		
	ΔB_1	ΔB_0	ΔB_2
3% silicon-iron, oriented	10	15	20
50% nickel-iron	10	15	20
79% nickel-iron	5	7.5	10
Supermalloy	5	7.5	10

The value of ΔB_0 was selected to be approximately one half the maximum flux density swing encountered in usual magnetic amplifier designs. Also, ΔB_1 approximates one third of the design ΔB; and ΔB_2 approximates two thirds of the design ΔB.

A4.3.3. In calibrating the flux voltmeter, which measures total flux change, to read flux density (in gausses) the manufacturer's published gross cross section area of the cores being tested and the following stacking factors shall be employed.

Tape Thickness, Mils	Stacking Factor
1/2	0.50
1	0.75
2	0.85
4 through 10	0.90
11 through 14	0.95

These stacking factors do not necessarily correspond to the manufacturer's stacking factors. As a result, measured values of B_m and $B_m - B_r$ will not agree with manufacturer's published data. To correlate test data, the following conversion must be made, and vice versa:

$$B' = \frac{BAk}{A'}$$

where

B' = flux density corresponding to the manufacturer's published core effective area
A' = manufacturer's published core effective area
k = stacking factor listed in the foregoing
A = published gross core cross-section area
B = flux density read from tester

The same stacking factor is employed in testing equivalent cores from various manufacturers in order that the cores may be tested with the same flux swings, and that the cores may be specified with one description. The tester actually measures flux change, which is the quantity of interest.

A4.4. Measurement of B_m: The peak induction (B_m) shall be measured at the peak magnetizing force specified in paragraph *A3.4.1*, employing full-wave sinusoidal excitation current and zero control current.

A4.5. Measurement of H_0: H_0 shall be measured in oersteds at the value of B_0 specified in paragraph *A4.3.2*, utilizing half-wave sinusoidal excitation current as specified in paragraph *A3.4.1*.

A4.6. Measurement of G in gausses per oersted is computed as follows:

$$G = \frac{\Delta B_2 - \Delta B_1}{H_2 - H_1} = \frac{\Delta B_2 - \Delta B_1}{\Delta H}$$

where ΔB_2 and ΔB_1 are specified in paragraph *A4.3.2* and ΔH is measured, utilizing half-wave sinusoidal excitation current as specified in paragraph *A3.4.1*.

A4.7. Measurement of $B_m - B_r$: $B_m - B_1$ should be measured utilizing zero control current and half-wave sinusoidal current excitation as specified in paragraph *A3.4.1*. *This measurement shall be made directly following the measurement of* B_m *in order to avoid errors resulting from magnetic history.*

A5.0. Differential Core Matching

In matching cores by the differential method, the tolerance of match shall be determined by measuring the differential output voltage between each core and a reference core at values of magnetizing force specified by the user. The difference so measured, as compared with the nominal peak induction of the core shall be a measure of the per-cent tolerance of match between the cores.

Fig. 3. Basic circuit for SCE core tester

SCE Core Test Method

B1.0. General Description

B1.1. The SCE test method provides for the measurement of four basic parameters of the saturated major dynamic sine current hysteresis loop of a core material for magnetic-amplifier applications. The core parameters measured are generally considered to be significant in determining the performance of the core material in the magnetic-amplifier type of application. These parameters are the a-c peak induction (corresponding to the a-c peak magnetizing force), the squareness ratio (ratio of residual induction to peak induction), the sine current coercive force, and the maximum differential permeability (maximum slope of the sides of the dynamic hysteresis loop).

B1.2. The test method described employs a relatively high impedance excitation source of sine voltage and known frequency, driving the core material under test into relative saturation while maintaining a sinusoidal exciting current. To facilitate rapid jigging of test cores of widely varying sizes, very few excitation and pickup turns are used. Instrumentation is provided for determining the peak magnetizing force, the peak induction, and for observing the output voltage versus exciting current waveform of the core material. Calibration means are provided whereby the sine current coercive force and the maximum differential permeability may be measured from the output voltage versus exciting current waveform. Provision is made for excitation of the core with a half-wave of rectified sine current to facilitate the measurement of flux density change (ΔB or $B_m - B_r$), from which the ratio of residual induction to peak induction may be calculated. Provision is also made for matching of cores on a differential basis.

B2.0. Test Circuit

B2.1. A test circuit such as that shown in Fig. 3 shall be used. The basic circuit consists of the components listed in the following.

B2.2. Same as paragraph *A2.2* of the CCFR method.

B2.3. Plug-in type test jig:

B2.3.1. Same as paragraph *A2.3.1* of the CCFR method.

B2.3.2. If a double or differential type of test jig is employed, the excitation windings of the two plug-in connectors shall have equal numbers of turns and shall be connected in series. The pickup windings of the two plug-in connectors shall have equal numbers of turns, and shall be connected in series opposition.

B2.3.3. Same as paragraph *A2.3.3* of the CCFR method.

B2.3.4. Provision for a noninductive voltage dropping resistor shall be made in series with the source and the excitation windings. The purpose of the dropping resistor is to provide a voltage that is proportional to the exciting current.

In 1957, a patent, which describes some of the circuitry for the SCE core test method, was granted under title 35, U.S. Code (1952, section 66).[4] Consequently, the patent disclosures may be used by or for the Government for government purposes without payment of royalties.

B2.4. Flux voltmeter: same as paragraph *A2.4* of the CCFR method.

B2.5. Oscilloscope:

B2.5.1. An oscilloscope with a minimum screen diameter of 5 inches shall be provided. The oscilloscope shall have d-c amplifiers for both vertical and horizontal signals. The amplifiers shall have adequate frequency response and sufficiently low phase shift[4] over the required frequency range so as to prevent distortion of the observed waveform in excess of one 2/100 of the screen diameter of the cathode-ray tube of the oscilloscope.

B2.5.2. If the output voltage versus exciting current loop characteristics are to be measured by means of scales on the face of the scope rather than by calibrated marker traces, then the linearity of the vertical and horizontal amplifiers and deflection systems shall be within one line width on the face of the oscilloscope.

B2.6. Ninety-degree phase shifter and calibrating attenuators:

B2.6.1. A source of sinusoidal voltage with less than 1% distortion shall be provided for the measurement of maximum differential permeability. This sinusoidal voltage, known as the ellipse voltage, shall be 90 degrees out of phase with the exciting current, and may be derived from the voltage across the excitation circuit dropping resistor by shifting its phase by 90 degrees. The function of the ellipse voltage is to provide a locus of constant differential permeability.

B2.6.2 The ellipse voltage shall be adjustable by separate calibrating and attenuating potentiometers to provide for calibration and measurement of maximum differential permeability readings in terms of gausses per oersted.

B2.7. D-c reference voltage sources:

B2.7.1. Two separate d-c voltage reference sources shall be provided, each with provision for measuring the reference voltage, and each with separate calibrating and attenuating potentiometers.

B2.7.2. One d-c reference voltage and attenuator shall be used for calibration of peak magnetizing force in oersteds when the exciting current waveform is not sufficiently distortion-free to use an rms ammeter for such calibration. The attenuator is also used in the direct measurement of sine current coercive force in oersteds.

B2.7.3. The other d-c reference voltage and attenuator shall be used for calibration of the ellipse voltage used in measuring the maximum differential permeability. The attenuator may also be used for measurement of the maximum differential permeability in the event that a distortion-free ellipse voltage is not obtainable under all test conditions.

B2.8. Rotating switch or phased synchronous choppers:

B2.8.1. A rotating double-pole multiposition switch shall be provided for displaying on the oscilloscope various sequences of the core output voltage versus exciting current, ellipse voltage versus exciting current, d-c reference voltage markers, and zero reference voltage markers.

B2.8.2. In lieu of a suitable rotating switch, two or more single-pole double-throw synchronous choppers may be used, properly phased, to apply the proper sequence of signals to the oscilloscope.

B2.8.3. The frequency of rotation of the switch, or driving frequency of the choppers, shall be not greater than one sixth of the fundamental core test frequency.

B3.0. EXCITATION REQUIREMENTS

B3.1. Voltage source:

B3.1.1. The voltage of the excitation source shall be sinusoidal, with a harmonic content of less than 10%.

B3.1.2. Same as paragraph *A3.1.2* of the CCFR method.

B3.1.3. Same as paragraph *A3.1.3* of the CCFR method.

B3.2. Excitation windings:

B3.2.1. Same as paragraph *A3.2.1* of the CCFR method.

B3.2.2. Same as paragraph *A3.2.2* of the CCFR method.

B3.2.3. Same as paragraph *A3.2.3* of the CCFR method.

B3.3. Exciting current:

B3.3.1. The exciting current shall be sinusoidal with a harmonic content of less than 5% at the value of current corresponding to the peak magnetizing force to be used for the core under test. Series resistance may be used to increase the impedance of the excitation source sufficiently to limit harmonics in the exciting current waveform for the smaller core sizes. When necessary, a series resonant filter shall be used to limit the maximum harmonic content of the exciting current to 5%.

B3.3.2. Suitable means for measuring the peak exciting current with an accuracy of 2% shall be provided. When the harmonic content of the exciting current is sufficiently low, a dynamometer type rms ammeter of at least 0.5% accuracy is recommended.

B3.3.3. Suitable means shall be provided for varying the exciting current to obtain the appropriate peak magnetizing force for the range of core sizes normally encountered. A variable autotransformer is usually satisfactory for this purpose.

B3.4. Peak magnetizing force:

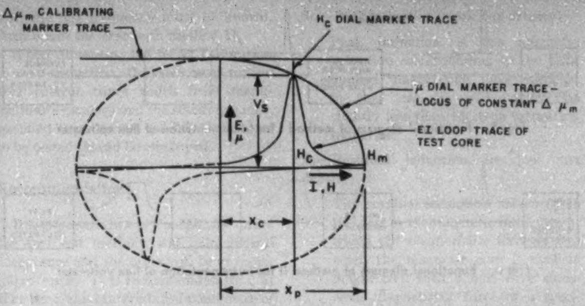
B3.4.1. The following peak magnetizing force shall be applied for the commonly used core materials. The value of peak magnetizing force applies to materials whose tape thickness is 6 mils or less, when tested at 400 cps or less, or whose tape thickness is from 6 to 14 mils or less, when tested at 60 cps.

Materials	Peak Magnetizing Force, Oersteds
3% silicon-iron (oriented)	3.0
50% nickel-iron (oriented)	1.0
79% nickel-iron	0.5
Supermalloy	0.25

B3.4.2. Same as paragraph *A3.4.2* of the CCFR method.

B3.4.3. When a dynamometer type rms ammeter is used to measure the exciting current, the peak magnetizing force shall be calculated from the equation

$$H_m = \frac{0.4\pi N_e I_m}{l} \text{ oersteds}$$



$\Delta\mu_m$ CALIBRATING MARKER TRACE
H_c DIAL MARKER TRACE
μ DIAL MARKER TRACE—LOCUS OF CONSTANT $\Delta\ \mu_m$

Fig. 4. Oscilloscope presentation of E I loop of test core, showing calibrating and measuring marker traces

where

N_e = number of excitation winding turns
I_m = peak exciting current, amperes = 1.414 I_{rms} for a pure sine wave
l = mean core length, cm

B3.4.4. When harmonics in the exciting current waveform are large enough to prevent the measurement of peak magnetizing force with the required accuracy, it may be measured from the oscilloscope display using a d-c reference voltage and calibrated attenuator, using the equation

$$H_p = \frac{0.4\pi N_p}{l} \times \frac{kV}{R} \text{ oersteds}$$

where

N_p = number of excitation winding turns
l = mean core length, cm
k = constant of attenuation of d-c reference voltage source
V = d-c reference voltage, volts
R = excitation circuit dropping resistor, ohms

B4.0. MEASUREMENT REQUIREMENTS

B4.1. Pickup windings:

B4.1.1. Same as paragraph *A4.1.1* of the CCFR method.

B4.1.2. Same as paragraph *A4.1.2* of the CCFR method.

B4.1.3. Same as paragraph *A4.1.3* of the CCFR method.

B4.1.4. Same as paragraph *A4.1.4* of the CCFR method.

B4.1.5. Same as paragraph *A4.1.5* of the CCFR method.

B4.1.6. Same as paragraph *A4.1.6* of the CCFR method.

B4.2. Core output measurements:

B4.2.1. The core output voltage waveform, as appearing on the pickup winding, may be measured by a number of methods to determine the dynamic hysteresis loop characteristics of the core under test.

B4.2.2. All instruments used in making output voltage waveform measurements shall have sufficiently high input impedance so as not to load the core output voltage. The minimum input impedance of this instrument shall be determined as

$$R > 2\pi f N_s \frac{2_A}{l} \Delta\mu_m \times 10^{-8}$$

where

N_s = pickup winding turns
A = core cross section area, cm^2
l = mean core length, cm
$\Delta\mu_m$ = maximum differential permeability of test core in gausses per oersted
f = test frequency, cps

B4.3. Measurement of peak induction or peak flux B_m:

B4.3.1. The measurement of peak induction shall be made by measuring the core output voltage with an average sensitive or integrating flux voltmeter (Fig. 3), using the peak magnetizing force specified in section *3.4.1.* The reading shall be calibrated directly in gausses, based on the core cross section area at a specific test frequency.

B4.4. Measurement of sine current coercive force H_c:

B4.4.1. Sine current coercive force measurements with this test method shall be made by displaying the core output voltage versus exciting current on an oscilloscope and measuring, by means of a calibrated potentiometer and dial marker trace, the horizontal distance between the voltage peaks of the oscilloscope display in relation to the known peak magnetizing force, as represented by the over-all horizontal width of the display (Fig. 4). The dynamic coercive force in oersteds is read directly from the H_c dial, Fig. 3, after adjusting the H_c dial marker to coincidence with the peak of the core output voltage (Fig. 4).

Note: It should be borne in mind that this measurement is a close representation of the true dynamic coercive force of the core material under test only if the material has approximately a rectangular dynamic hysteresis loop. Under these conditions the peak of the induced core output voltage waveform corresponds with the true dynamic coercive force within a few per cent. When nonrectangular dynamic hysteresis loop materials are being measured, however, the peak of the output voltage wave may depart from the true coercive force value by a considerable amount, and the value measured is the H at $\Delta\mu_m$. This value will generally be somewhat different than the true H_c value, but may be used and specified in the same manner as the H_c value as long as the test conditions and the test results obtained are clearly defined.

B4.5. Measurements of maximum differential permeability ($\Delta\mu_m$):

B4.5.1. The measurement of maximum differential permeability shall be made by displaying the core output voltage versus exciting current on an oscilloscope and measuring, by means of a calibrated potentiometer and dial marker trace, the peak value of the output voltage. The maximum differential permeability in gausses per oersteds may be read directly from the μ dial (Fig. 3) after adjusting the μ dial marker to coincidence with the peak of the core output voltage (Fig. 4).

B4.5.2. Calibration of maximum differential permeability shall be accomplished using a d-c reference voltage and calibrated attenuator. When the $\Delta\mu_m$ calibrating marker trace is adjusted to coincidence with the peak value of the ellipse voltage, the maximum differential permeability in gausses per oersted may be calibrated using the equation

$$\Delta\mu_m = \frac{k'V'}{N_s A} \times \frac{l}{0.4\pi N_e I_m} \times \frac{10^8}{w \cos wt}$$

where

N_e = number of excitation turns
N_2 = number of pickup turns
A = nominal core area, cm^3
l = mean core length, cm
I_m = peak excitation current
  $= 1.414\, I_{rms}$ for a pure sine wave
$w = 2\pi \times$ test frequency
V' = d-c reference voltage, volts
k' = attenuation constant of reference voltage attenuator

by setting $wt = 0$ and substituting the appropriate contents into the equation.

B4.5.3. An alternative calibration of maximum differential permeability may be made by adjusting the $\Delta\mu_m$ calibrating marker to coincidence with the peak of the core output voltage wave, and using the equation of *B4.5.2* by setting $wt = (\sin^{-1} H_c/H_m)$ and substituting the appropriate constants in the equation.

B4.6. Measurement of squareness; ratio of residual to peak: Induction (ΔB or B_r/B_m).

B4.6.1. The measurement of squareness shall be made by measuring the change in induction ($B_m - B_r$) with an average sensitive or integrating flux voltmeter with a half-wave sinusoidal excitation whose peak magnetizing force corresponds to that specified in section *B3.4.1.* This measurement of the change in induction shall be made in terms of gausses. *This measurement shall be made directly following the measurement of B_m in order to avoid errors resulting from magnetic history.*

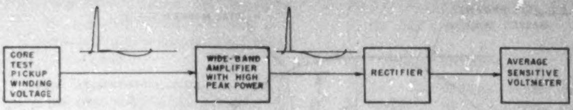
B4.6.2. When the ratio of residual to peak induction is required, rather than ($B_m - B_r$), it may be calculated as

$$\frac{B_r}{B_m} = \frac{B_m - (B_m - B_r)}{B_m} = 1 - \frac{B_m - B_r}{B_m}$$

with the value of peak induction, B_m, measured as in section *B4.3.1.*

B5.0. DIFFERENTIAL CORE MATCHING

B5.1. When matching of cores by the differential method is desired, the over-all match shall be determined as a percentage, plus or minus, using one of the cores in each matched set as a reference. The tolerance of match shall be determined by measuring the differential output voltage between each core and the reference core with an average sensitive or integrating flux voltmeter; see Fig. 3. The difference in induction so measured, as compared with B_m of the reference core, shall be a measure of the per-cent tolerance of match between the cores.



CORE TEST PICKUP WINDING VOLTAGE
WIDE-BAND AMPLIFIER WITH HIGH PEAK POWER
RECTIFIER
AVERAGE SENSITIVE VOLTMETER

Fig. 5. Functional diagram of method I for instrumentation of flux voltmeter

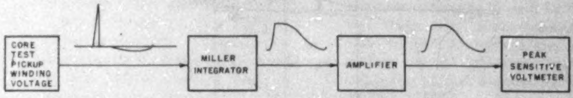


Fig. 6. Functional diagram of method II for instrumentation of flux voltmeter

Flux Voltmeter Instrumentation

The output of the core test circuits described in the foregoing is obtained from a pickup winding on the core test jig. The instantaneous induced voltage in the pickup winding is proportional to the rate of change of flux. This instantaneous induced voltage is fed into a flux voltmeter. The function of the flux voltmeter is to integrate the induced voltage and amplify as necessary to give a meter reading proportional to the flux change.

Two methods of flux voltmeter instrumentation have been used. Both methods are theoretically correct. The difference in the two methods of instrumentation is in the means of accomplishing the integration and the type of amplifier required. The first method,[6] is to amplify the induced voltage, rectify it, and read the output on an average sensitive voltmeter. The second method[7] is to integrate the induced voltage, then amplify it, and read the output on a peak sensitive voltmeter. In method I the integration is accomplished by the averaging action of the meter. In method II the integration is accomplished by an integrating network. A detailed description of each method has been published in the literature.[6,7] Only a short summary of each will be given here.

A functional diagram of method I is shown in Fig. 5. The induced voltage is amplified by a wide-band vacuum-tube amplifier. A typical waveform of the type encountered during core tests is shown in Fig. 5. The ratio of peak to average voltage may be as high as 50 to 1. For accurate measurements the wide-band amplifier must have sufficient peak-handling capabilities to reproduce faithfully these high peak voltages. Therefore, special consideration must be given in selecting this amplifier to be certain that it does not saturate on these high peak inputs. The output of the amplifier is rectified and fed into an average sensitive (d'Arsonval) voltmeter.

A functional diagram of the method II is shown in Fig. 6. The induced voltage is fed into a Miller-type integrating amplifier circuit which is equivalent functionally to a resistance-capacitance voltage integrator and subsequent amplifier. The integrated voltage is amplified by a conventional linear amplifier. It is evident from an examination of the waveforms shown in Fig. 6 that the amplifier requirements are not as stringent for method II as they are for method I, since there are no high peaks in the integrated voltage waveform. The output of the amplifier is fed into a peak-sensitive voltmeter. The peak-sensitive voltmeter may be constructed from a voltage doubler rectifier circuit with a capacitor across the output which charges to the peak-to-peak output. This peak output can then be metered with an average sensitive (d'Arsonval) voltmeter.

Since both meters measure the total flux change in a core during each cycle of the excitation frequency, the meters can best be calibrated by utilizing a core in which the total flux change for a given excitation is known. The excitation must be sufficient to drive the core well into saturation. A Supermalloy core excited with a peak excitation of 10 oersteds is suggested. The total flux change, when excited from minus to plus 10 oersteds may be determined by normal d-c methods.

The calibration core may be placed in the test jig and excited with the magnetizing force for which the flux swing of the core is known. The meter may then be calibrated in terms of the known flux change.

With method I the meter reading is proportional only to average voltage. When converting the reading to units of flux change, both during calibration and test, the test frequency must be known. Such is not the case with method II.

When converting the meter calibration to read induction, the core cross-section area (height times width from manufacturer's catalog) and the stacking factor, specified in paragraph *A4.3.3*, of the cores to be tested should be employed.

Recommendations

It is expected that as time passes, one of the two test methods will gain general acceptance and the other will be of minor importance. It is recommended that, at that time, the Materials Subcommittee of the Magnetic Amplifier Committee review this specification with an aim of having only one standard test circuit. Specified test conditions, such as peak magnetizing force, should be reviewed in the light of making them applicable to only one test circuit rather than to two.

Glossary of Special Terms

The following list defines certain special terms used in this paper. An effort has been made to make these definitions compatible with the American Standards Association definitions of electrical terms,[8] and the proposed standard terms and definitions for magnetic amplifiers of the AIEE Magnetic Amplifier Committee.

H_m—Peak magnetizing force

> Peak magnetizing force is the maximum value of applied magnetomotive force per mean length of path of the core.

B_m—Peak induction (peak flux density)

> Peak induction is the magnetic induction corresponding to the peak applied magnetizing force specified in this test. It will usually be slightly less than the true saturation induction.

B_r—Residual induction (residual flux density)

> The residual induction measured in this test is the magnetic induction at which the magnetizing force is zero when the magnetic core is cyclicly magnetized with a half-wave sinusoidal magnetizing force of a specified peak magnitude. This use of the term residual induction differs from the standard definition which requires symmetrically cyclicly magnetized conditions.

Sine current magnetizing force

> The sine current magnetizing force is the applied magnetomotive force per unit length for a core symmetrically cyclicly magnetized with a sinusoidal current.

$\Delta\mu$—Sine current differential permeability

> The sine current differential permeability is the slope of the sides of the dynamic hysteresis loop obtained with a sine current magnetizing force.

$\Delta\mu_m$—Maximum sine current differential permeability

> The maximum value of sine current differential permeability obtained with a specified sine current magnetizing force.

H_c—Sine current coercive force

> The sine current coercive force is the instantaneous value of sine current magnetizing force at which the dynamic hysteresis loop passes through zero induction.

ΔB—Delta induction (delta flux density)

> Delta induction is the change in induction (flux density) when a core is in a cyclicly magnetized condition.

H_0, H_1, H_2,—Bias points; see Fig. 1

ΔB_0, ΔB_1, ΔB_2,—Independent variables; see Fig. 1

G—Gain; see Fig. 1

Transistor-Oscillator Induction-Motor Drive

W. H. CARD
NONMEMBER AIEE

Synopsis: Transistor and saturable-core-transformer oscillators driving small 2-phase induction motors provide, in effect, a d-c motor without a commutator. The inductive motor load on the oscillators requires that the transistors carry current in both directions and this is aided by shunting the transistors with rectifiers. Simple interconnection of two oscillators provides the 2-phase system. Operation of an experimental drive in the range from 125 to 500 cycles per second resembles behavior of a separately excited d-c motor except that motor shaft rotation is not reversed by reversing the d-c source. The harmonics in the square-wave motor voltages usually have negligible effect.

ORDINARY d-c machines with commutators have been highly developed but the risk of brush-arcing in explosive atmospheres and rapid brush wear especially at high altitudes makes attractive the idea of a d-c machine without a commutator. Power transistors now available have good switching properties so there is the possibility of performing the switching function of the commutator by means of transistors. However, rather than directly modifying a d-c machine to replace the commutator with transistor circuits, a simpler scheme appears to be to build power oscillators to drive conventional a-c machines. A 2-phase transistor oscillator to drive a 2-phase induction motor is described here.

In the experimental system reported here four power transistors, four recti-

fiers, two saturable transformers, and a single d-c source are used to drive a small 2-phase servomotor. The resulting performance is somewhat like that of a separately excited d-c motor except that rotation is not reversed by reversing the supply voltage. One advantage of the system over conventional 2-phase servomotor drives is that there is no fixed-phase power loss. The important contributions of this paper are believed to be the novel phase-locking connections and the calculated and experimental motor performance curves. Subjects for further investigation are the behavior of other types of a-c motors with the same drive and the generator behavior of the system.

Transistor Power Oscillator

Modified forms of the transistor square-wave oscillator described by Royer[1] are used to drive the motor phases. The circuit shown in Fig. 1(A) differs from Royer's circuit in that rectifiers are connected across the transistors and the load is connected across the transformer main winding (N_m, N_m') rather than to a separate winding. The reasons for this load connection and the phase-locking of two oscillators are explained in the next section. This section reviews the operation of the circuit and discusses the function of the rectifiers when driving inductive loads.

The operation of the oscillator has been explained in terms of the switching behavior of the transistors.[1,2] Provided the base-circuit drive on the transistors from the feedback winding (N_f,N_f') is sufficient to drive the transistors to short circuit, the oscillator may be represented by the circuit model of Fig. 1(B) with the transistors and parallel rectifiers replaced by switches. The output voltage e_0 is a square wave as shown in Fig. 1(C). If a square-loop-core transformer is used and switching occurs when the core saturates, the frequency is given by

$$f=\frac{1}{T}=\frac{E}{4N_m\phi_m} \qquad (1)$$

where ϕ_m is the saturation core flux. Frequency and output voltage are ordinarily little changed for resistive or inductive loads, provided the load current does not approach too closely the limit set by transistor gain and the feedback circuit. The oscillator output is nearly ideal for driving an ordinary a-c motor because, for varying voltage and frequency proportional to voltage, the magnetic saturation in the motor remains nearly constant.

If the oscillator is used to drive an inductive load such as a motor, the load current cannot change magnitude instantaneously, hence a path must be provided in the oscillator circuit to allow the load current to continue to flow when the square-wave oscillator voltage switches polarity. Assuming perfect coupling between N_m and N_m', Fig. 2 shows the distribution of the load components of current for an inductive load at instants before and after switching for the circuit model of Fig. 1(B). Since many available power transistors have less current gain in the inverted than the normal direction, the rectifiers shown in Fig. 1(A) are used to carry at least part of the load current for a short interval after each voltage reversal.

At the instant after switching, the source current is reversed as shown in Fig. 2(B). This means that some of the stored energy in the reactive load is fed back into the source, so the source must be capable of receiving as well as supplying energy. The situation is similar to that of an ordinary a-c reactive load where the instantaneous power flow is negative during part of the cycle.

The transformer windings N_m and N_m' should have good coupling because any leakage reactance results in increased transistor dissipation.[2] It is important to note that increasing transformer leakage reactance increases transistor dissipation, but adding load reactance mainly requires that the "switch" carry current in either direction.

Two-Phase Oscillator

Each motor phase is driven by an oscillator, and the two oscillators are locked in synchronism with their voltages in quadrature. This section describes the phase-locking connection used. Other schemes have been used for phase-locking[3] and it is possible to build oscillators that are intrinsically polyphase,[4] but the method reported here has the virtue of simplicity.

Fig. 3(A) shows a simplified circuit model of the system used. The feedback windings are not shown, the transistors and parallel rectifiers are replaced by the switches A, B, C, and D, and the transformers are assumed to have square-

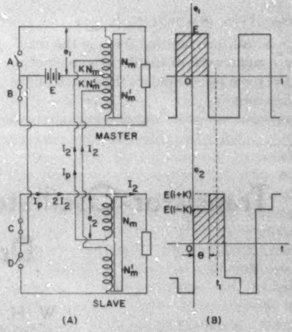

Fig. 3. Two-phase oscillator

A—Simplified circuit model
B—Transformer voltage waveform

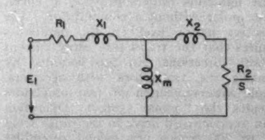

Fig. 4. Induction-motor equivalent circuit

loop cores with negligible loop width. The master oscillator is like the one discussed in the preceding section except for two additional taps at KN_m and KN_m' on the transformer main winding. The slave oscillator is supplied from the same source as the master oscillator and is otherwise the same except that instead of returning the center point on the transformer main winding to the source, the winding is split and returned to the source through the taps on the master oscillator transformer.

Consider first steady-state operation with the two oscillators operating at the same frequency and in phase quadrature. The two oscillator transformer voltage waveforms are shown in Fig. 3(B). The master oscillator waveform is undisturbed by the interconnection, and the (shaded) volt-second area per half-cycle is determined as usual by the saturation volt-seconds of the square-loop-core transformer. In each half-cycle the slave oscillator transformer voltage is first reduced by the factor K, then increased by the factor K of the master oscillator transformer voltage. The (shaded) volt-second area is the same as that of the master oscillator. Thus, if the transformers have the same volt-second area as viewed from N_m, N_m', the requirements are met for both oscillators to operate at the same frequency.

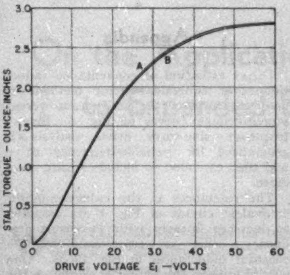

Fig. 5. Calculated stall torque versus drive voltage for 400-cycle servomotor with square-wave drive and frequency proportional to voltage. Curve A neglects and curve B includes effect of harmonics

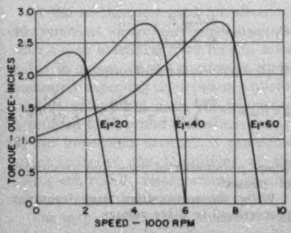

Fig. 6. Calculated speed-torque curves for low-rotor-resistance induction motor with frequency proportional to drive voltage

Provided the two oscillators have the same frequency they will lock in phase quadrature because any change of phase brings compensating action. For example, suppose the slave oscillator tends to speed up. Then in Fig. 3(B), θ becomes greater so that the slave oscillator transformer voltage $E(1-K)$ is applied for more than a quarter period and $E(1+K)$ for less than a quarter period. Since the volt-second area is fixed, the half-period is lengthened and the slave oscillator slows down. In the same way, if the slave oscillator tends to slow down it is speeded up.

Except at the instant of switching the slave oscillator does not appreciably load the master oscillator. Consider time t_1 when switches B and C are closed. The load-component currents I_2 of the slave oscillator are shown in Fig. 3(A). Current I_2 produces no net ampere-turns on the master oscillator transformer.

At the instant before slave oscillator switching, the current in switch C increases by some amount I_p because the slave transformer saturates. This component of current does load the master oscillator and flows through the master oscillator transformer in a direction to increase the required current through switch B. Consequently, there is some tendency for the slave oscillator to cause premature switching of the master oscillator.

The "stepped" waveform of the slave oscillator transformer voltage does not affect the slave oscillator load voltage. It remains square and of the same magnitude as that of the master oscillator. However the stepped waveform appears in the slave oscillator feedback winding, hence the transistor base current is affected. This means that K should be small, for if K approaches unity then during the first quarter cycle of the slave oscillator there would be little base current to hold the transistor (switch C) at short circuit. In the experimental circuit $K=0.25$ is used.

While it may be possible to use the phase-locking principle described here if the loads are connected to separate windings on the two transformers, there are two drawbacks. If the slave oscillator has a separate load winding, net ampere-turns are applied by the slave oscillator to the master oscillator transformer.

Also, the slave oscillator load voltage has a stepped waveform like Fig. 3(B) instead of the square waveform.

Calculated Motor Performance

Two special problems must be considered when the 2-phase transistor oscillator described in the foregoing is used to drive an induction motor. First, motor performance with square-wave voltage drive is discussed. Second, since the oscillator frequency and output voltage both vary directly with source voltage, performance with this type of drive is reviewed. Calculated curves for low-slip and high-slip motors illustrate the discussion.

The induction-motor equivalent circuit shown in Fig. 4 is used to predict motor behavior. The resistances are assumed constant regardless of speed and frequency, and the reactances are assumed to vary directly with frequency. Torque calculation at any particular drive voltage and frequency is made by conventional methods.[5]

Induction-motor operation with square-wave voltage drive differs from that with sinusoidal drive in two respects. When comparing performance with a sine-wave voltage drive e_1 and a square-wave voltage drive e_2 which has a fundamental component equal to e_1, the power input will be greater and the torque less.

If equal resistances are driven by e_1 and e_2 the ratio of power inputs p_1 and p_2 is

$$p_1/p_2=(2\sqrt{2}/\pi)^2=1.22 \qquad (2$$

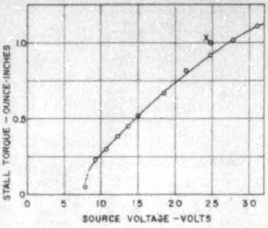

Fig. 8. Measured stall torque versus source voltage for 400-cycle servomotor

Since the motor terminal impedance increases with frequency, the harmonic currents are less than for a resistance. Hence the motor electric power input is never more than 22% greater than for the corresponding sinusoidal drive.

By superposition the total torque is the algebraic sum of the torques contributed by the harmonics. For 2-phase drive with identical but nonsinusoidal voltages in quadrature, the fundamental, fifth, ninth, etc., harmonics contribute positive torques and the third, seventh, eleventh, etc., harmonics contribute negative torques. Analysis of the equivalent circuit (see the Appendix) shows that the third-harmonic stall torque approaches one third, and the sum of the stall torques approaches $\pi/4=0.785$ of the fundamental alone for the worst condition, which is very low frequency.

Calculated performance of a high-slip 2-phase 8-pole induction motor (servomotor) with square-wave drive is shown in Fig. 5. The motor parameters at 400 cycles are $R_1=10$ ohms, $X_1=32$ ohms, $X_m=64$ ohms, $X_2=32$ ohms, $R_2=70$ ohms. The drive frequency f varies as the square-wave voltage amplitude E_1 by $f=10E_1$. In the low-voltage region, the stall torque increases as the third power of drive voltage because of the short-circuiting effect of the magnetizing reactance. The component torques caused by square-wave voltage harmonics decrease the stall torque by a nearly constant amount throughout the range up to rated voltage and frequency. The system is not reversible as is a separately excited d-c motor but, except at low voltage, has stall torque nearly proportional to drive voltage.

Calculated speed-torque curves, neglecting voltage harmonics, for a low-rotor-resistance induction motor are shown in Fig. 6. Except for $R_2=15$ ohms, the same drive and motor parameters are used here as in Fig. 5. The maximum torque and slip speed for maximum torque are nearly constants independent of drive voltage. By increasing the drive voltage from zero, nearly maximum torque is available for starting. At low torque the speed is nearly proportional to drive voltage as in a separately excited d-c motor.

Experimental Results

The experimental oscillator shown in Fig. 7 operates at about 400 cycles per second with a 24-volt source. The collector-to-collector square-wave voltage of about 44 volts amplitude indicates transistor and winding resistance drop of about 2 volts referred to the battery, and a fundamental output voltage of $44\ (2\sqrt{2}/\pi)=40$ volts. Frequency is variable from 125 cycles, or lower on light load, to 500 cycles where maximum-rated collector-to-emitter voltage of 60 volts is reached. The rectifiers effectively clip the voltage spikes that otherwise appear on the output square wave. The transformers used are larger than necessary and improved oscillator design should extend the frequency range.

Neither cores nor transistors are specially matched in the 2-phase oscillator. Because the two oscillators, operated independently, have frequencies about 5% different, they lock in synchronism but not in phase quadrature. However, sufficient adjustment is possible by varying R_1 and R_2 to get good quadrature operation over the operating range.

The 2-phase oscillator was used to drive a small 400-cycle 8-pole servomotor requiring 6.2 watts per phase at 40 volts per phase. The stall-torque versus source-voltage curve shown in Fig. 8 agrees in form with the calculated curve shown in Fig. 5. The point X shows a test for sine-wave drive with voltage equal to the square-wave fundamental indicating the voltage harmonics have a small effect, as predicted.

To verify the theory for a low-rotor-resistance machine, a 60-cycle motor (Diehl *FP-25*) was driven at frequencies up to 500 cycles. (The voltage at 60 cycles was about 3 volts instead of 22 volts rated for the motor.) The speed-torque curves shown in Fig. 9 indicated the general behavior of nearly constant pull-out torque as predicted by the theoretical plot in Fig. 6.

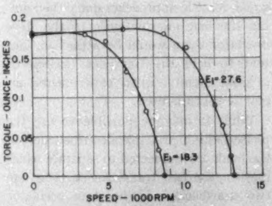

Fig. 9. Measured speed-torque curves for 60-cycle servomotor

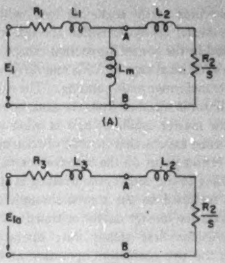

Fig. 10. Modified induction-motor equivalent circuits

Appendix

Direct extension of conventional induction-motor equivalent-circuit methods is used to calculate the stall-torque versus source-voltage curves of Fig. 5. Single-frequency sine-wave drive analysis is generalized for variable-frequency drive and then extended to include square-wave drive.

The reactances in the induction-motor equivalent circuit of Fig. 4 are assumed to increase linearly with increasing frequency, hence are represented by the constant inductances in Fig. 10(A). One way to analyze this circuit is to replace the network to the left of nodes A and B by the Thévenin equivalent circuit shown in Fig. 10(B) by setting

$$E_{1a}=\left|\frac{j\omega L_m}{R_1+j\omega(L_1+L_m)}\right|E_1 \tag{3}$$

and

$$R_3+j\omega L_3=\frac{j\omega L_m(R_1+j\omega L_1)}{R_1+j\omega(L_1+L_m)} \tag{4}$$

With slip $S=1$, the stall torque is

$$T_1(E_1,\omega)=\frac{pq}{2\omega}\left\{\left|\frac{E_{1a}}{R_3+R_2+j\omega(L_3+L_2)}\right|\right\}^2 R_2 \tag{5}$$

where p = number of poles and q = number of phases.

With sine-wave drive and frequency proportional to drive voltage

$$\omega=cE_1 \tag{6}$$

and the curve of stall torque versus supply voltage (Fig. 5 curve A) is plotted by

Vol. 7
Pt. 1
1958

using equations 3 through 6 for a succession of values of E_1.

For a single-frequency square-wave drive of amplitude $\pi E_1/2\sqrt{2}$, the drive voltage may be represented by the Fourier series

$$e_1(t)=\sqrt{2}E_1\left(\cos\omega t-\frac{1}{3}\cos 3\omega t+\frac{1}{5}\cos 5\omega t\ldots\right) \quad (7)$$

Each component contributes torque and these are calculated individually and summed algebraically.

Of special interest is the shape of the stall-torque versus drive-voltage curve for very low voltage. First for sine-wave drive, from equations 3 through 6,

$$E_{1a}\approx\left|\frac{j\omega L_m}{R_1}\right|E_1 \quad (8)$$

$$E_{1a}\approx\frac{cL_m}{R_1}E_1^2 \quad (9)$$

Since

$$R_3+j\omega L_3\ll R_2 \quad (10)$$

the stall torque at low voltage is

$$T_1\approx\frac{pq}{2cE_1}\left(\frac{cL_mE_1^2}{R_1R_2}\right)^2R_2 \quad (11)$$

$$T_1\approx\frac{pqcL_m^2}{2R_1^2R_2}E_1^3 \quad (12)$$

indicating a very slow initial rise of stall torque with increasing supply voltage.

Now consider the extreme case of square-wave drive of such low voltage and frequency that even the harmonics are within the range of approximate validity of equation 9. The nth harmonic of the square wave has rms value E_1/n and the Thévenin equivalent voltage for the nth harmonic is

$$E_{na}\approx\left|\frac{jn\omega L_m}{R_1}\right|\frac{E_1}{n} \quad (13)$$

$$E_{na}\approx E_{1a} \quad (14)$$

Hence from equations 5, 10, and 14 the ratio of nth-harmonic stall torque to fundamental stall torque is

$$\left|\frac{T_n}{T_1}\right|\approx\frac{\frac{pq}{2n\omega}\left(\frac{E_{1a}}{R_2}\right)^2R_2}{\frac{pq}{2\omega}\left(\frac{E_{1a}}{R_2}\right)^2R_2} \quad (15)$$

$$\left|\frac{T_n}{T_1}\right|\approx\frac{1}{n} \quad (16)$$

All the harmonic stall torques are summed algebraically to get the total stall torque

$$T=T_1\left(1-\frac{1}{3}+\frac{1}{5}\ldots\right)=\frac{\pi}{4}T_1$$

On the Application of Zener Diodes to Expanded Scale Instruments

A. J. CORSON
MEMBER AIEE

WITH THE ADVENT of closer regulation of industrial electric circuits comes the need for high-accuracy limited-range measurement about a mean value, representative of normal circuit conditions. This applies with particular force to voltage and frequency measurement, and there are many instances in which it is equally true in the measurement of current and power.

Of the mechanisms used for electrical measurement, all are inherently long range with a span extending from zero to some value in excess of the maximum to be measured, expecting the frequency meter. In this exceptional case, the frequency is reduced to a current difference or ratio, by an impedance network, a procedure which removes the limitations of the spring-controlled measurement mechanism in respect to measurement span.

The span of voltmeters, ammeters, and wattmeters may be reduced and the sensitivity increased by prestressing the control spring in the down-scale direction. A voltage (for example, V_1) is required to deflect the movement back to zero, and the voltmeter may then be calibrated over the range V_2-V_1, where V_2 is the voltage required for full-scale deflection. This expedient originates several problems, however, notably, loss of mechanical zero as a check on the condition of the instrument, loss of independence of zero and full-scale adjustments, and loss in restoring-torque gradient. For these reasons, the gain in sensitivity, or readability, is seldom accompanied by a commensurate gain in accuracy. Indeed, unless the instrument is designed for suppressed-zero operation, this method is equivalent to simply magnifying a limited portion of the scale range.

In January 1956, E. E. Helin of the Bell Laboratories suggested the use of the Zener voltage of silicon diodes for expanded scale voltmeters and demonstrated a series d-c circuit in which the reversed diode blocked the instrument current at values below the desired measurement range. This voltmeter circuit was simple and effective, and resulted in a 4-to-1 sensitivity increase, using a standard microammeter calibrated in volts. We then proceeded with a study of the use of Zener diodes in a-c voltage, current, and frequency measurement. The results show that limited-range high-accuracy measurement can be achieved wherever the need for it may exist.

The Silicon Diode

In 1952, Pearson and Sawyer[1] of the Bell Laboratories reported the preparation of a new type of p-n junction silicon diode by alloying acceptor of donor impurities with n- or p-type silicon. The unique features of this diode were: 1. reverse currents as low as 10^{-10} amperes, 2. rectification ratios as high as 10^8 at one volt, 3. a stable Zener characteristic in which $\Delta(\log I)/\Delta(\log V)$ was as high as 1,500 over several decades of current, and 4. ability to operate at ambient temperatures as high as 300 C (degrees centigrade).

In 1954, D. H. Smith,[2] also of the Bell Laboratories, proposed the use of the Zener voltage as a reference standard and

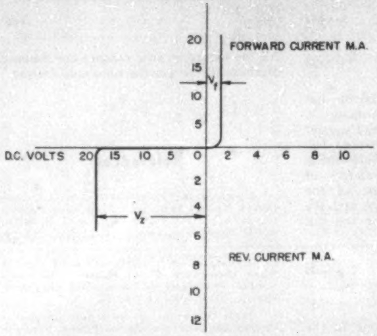

Fig. 1. D-c voltage current characteristic of silicon diode

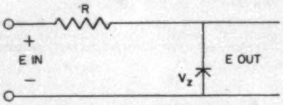

Fig. 2 (left). D-c voltage reference circuit using diode reverse current characteristic

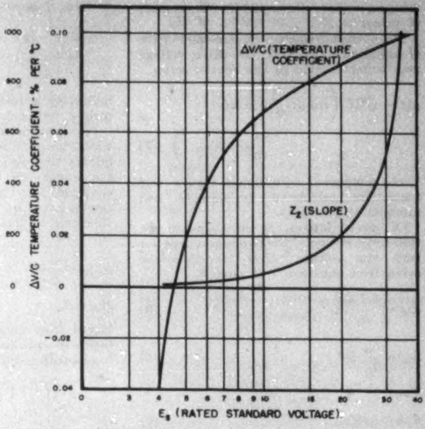

Fig. 3. Impedance and temperature coefficient as function of rates voltage for silicon fused-alloy junction diodes

presented data on temperature coefficient, resistance, and breakdown voltage. The availability of such diodes was subsequently announced by several manufacturers, notably National Semiconductor Products and Transitron Electronic Corporation.

The typical d-c voltage-current characteristic of a silicon diode is shown in Fig. 1. When used for voltage reference, the essential parameters are: 1. The Zener voltage drop V_z, 2. the impedance in both the nonconducting and conducting reverse voltage range, 3. temperature coefficient, and 4. allowable dissipation.

A typical d-c voltage-reference circuit is shown in Fig. 2. The value of the current-limiting resistor R is chosen so that the Zener current $I_z \cong E-V_z/R$ will bias the diode to a satisfactory value as determined primarily by the allowable Zener impedance and secondarily by the desired (exact) Zener voltage. The temperature coefficient depends on the voltage rating as shown in Fig. 3. It is negligible for 4- to 5-volt diodes and is as high as 0.10% per C for 40-volt diodes. Since the characteristic of any one voltage rating is linear, compensation can be used if higher Zener voltages are mandatory. A better but more expensive method of obtaining higher reference voltages is by use of several low-voltage diodes in series. This procedure reduces the Zener impedance as well as the temperature coefficient. The dissipation capacity of all diodes was approximately 150 milliwatts with a recommended derating of one milliwatt per C above a 25 C ambient temperature. Voltage ranges of 5 to 18 volts are available. The stability of these diodes, in relation to the requirements of this application, appears to be excellent. No observable drift has been noted in 10 months' observation of several of them.

When connected to an a-c source through a series resistor, the reverse voltage drop across the diode is the applied voltage until the applied voltage equals the Zener voltage. The Zener voltage is then held until the applied voltage decreases to Zener value, as shown in Fig. 4. At that point the diode again becomes an open circuit, and the voltage drop is coincident with the applied voltage until reversal of the voltage wave drop takes place. (It is assumed in this discussion that the forward current is blocked by another rectifier.) It follows that the average value of Zener voltage is a function of the peak applied voltage, increasing as the applied voltage increases from V_0 and V_0'. In order to establish the limits of satisfactory regulation, the average clipped voltage is derived in terms of the peak applied and Zener voltages as follows. Let

V_z = Zener voltage (see Fig. 5)
V_a = average of clipped voltage
V_0 = peak applied voltage
$e = V_0 \sin$

$$V_a=\frac{1}{\pi}\left[2\int_0^{\alpha} V_0' \sin \alpha d_\alpha + V_z(\pi-2\alpha')\right]$$

which after integration and reduction results in:

$$V_a=\frac{V_0[2(1\sqrt{1-K^2})+K(\pi-2\sin^{-1}K)]}{\pi}$$

where

$K=V_z/V_0$

The plot of this relationship (Fig. 5) shows that this method of stabilization becomes more effective as the ratio of peak applied to Zener voltage is increased. Exact stabilization is unnecessary in such applications as voltage and frequency measurement, nevertheless, we found it desirable to maintain V_0/V_z ratios of 5 or better to get effective results.

Circuit for A-C Expanded Scale Voltmeters

After a study of the possibilities, it was decided to evaluate the diode circuit shown in Fig. 6(A) for a-c voltage meas-

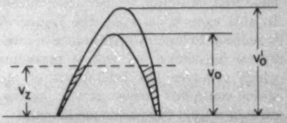

Fig. 4. Relationship between applied sinusoidal voltage and the regulated voltage. Regulation is inexact because of addition of crosshatched areas as applied voltage is increased from E_{o1} to E_{o2}

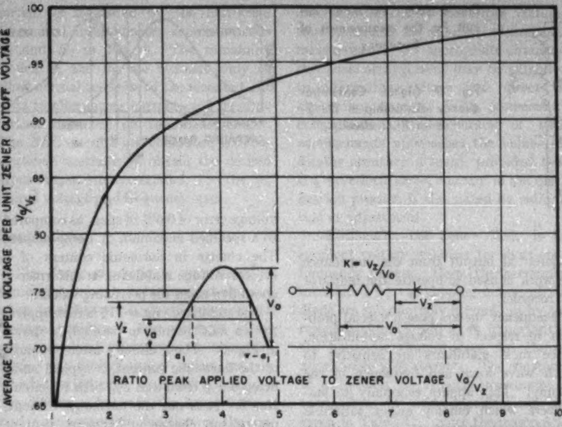

Fig. 5. Relationship between average zener voltage and ratio of peak applied to Zener cutoff voltage (equation)

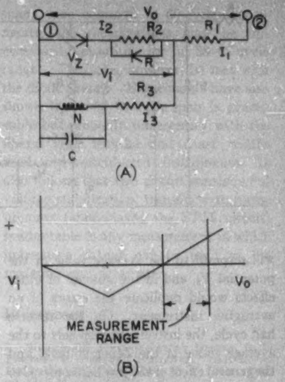

Fig. 6. A—Circuit for limited range voltage measurement. 6. B—Input-output characteristic of circuit in A

urement. The circuit element N represents a zero-left, d-c milliammeter which together with resistor R_3 and capacitor C, measures the average d-c component of the voltage V_i. It is evident that this component will be the difference of the forward and reverse half cycles of V_i as a sinusoidal voltage V_0 is applied to the circuit. Since the forward rectifier voltages will cancel each other, we have with terminal 1 positive:

$$V_i = \frac{V_0}{1.11}\left(\frac{R_2R_3}{R_1(R_2+R_3)}\right) + R_2R_3$$

where V_i = average half cycle voltage, V_0 = half-cycle rms voltage, and other quantities are as shown in Fig. 6(A).

On the reverse half cycle $V_i' = V_a$ and the net d-c component is

$$V_i' = \frac{V_0}{1.11}\left(\frac{R_2R_3}{R_1(R_2+R_3)+R_2R_3}\right) - V_a$$

This relationship, plotted in Fig. 6(B) shows that the instrument will indicate zero at zero voltage, deflect down scale for voltage values below the measurement range, return to zero at the beginning of this range and defect to full scale at maximum voltage.

This circuit was experimentally evaluated for the following application:

Measurement range	110–130 volts
Frequency	60 cycles
Output instrument	9-inch rectangular switchboard 1-milliampere milliammeter
Scale length	14.2 inches
Volt-ampere input	10 maximum

The results were, in general, satisfactory. The only nonlinearity in the circuit, that of the Zener characteristic, causes a small expansion of the scale distribution at higher voltages. This is advantageous rather than the reverse, since it facilitates a scale design which avoids ambiguity of the zero with the initial scale interval. Specifically, normal voltage is marked at the 12-o'clock position, then equal voltage increments on either side will locate the minimum voltage slightly above zero as shown in Fig. 7.

Since the output instrument has an accuracy rating of 1% of span, or 0.1 volt in this instance, the only design problems are optimization of the input-output characteristic and elimination of or compensation for sources of error. Excellent temperature performance can be achieved by use of low-voltage (6–8 volt) Zener diodes and compensation for the residual error by a thermistor in parallel with a small portion of the resistor R_1. The thermistor is chosen to cause a slight increase in the forward current (terminal 1 positive) of such magnitude as to cancel the effect of the positive Zener coefficient. If several, say 4, Zener diodes are used, it is advisable to by-pass them with a duplicate of the reverse current diode, thus eliminating the cumulative effect of the forward Zener resistances. While relatively exact compensation can be achieved in any one instrument, component variation would limit the effectiveness of compensation without individual adjustment. It is probable that a coefficient of ±0.03%/C can be maintained, as compared to the American Standards Association (ASA) *C39.1* value of 0.075%/C.

The frequency effect at 60 cps (cycles per second) is negligible with no discernible error resulting from a ±10% change in frequency.

The wave-form effect is appreciable but notably less than that of average reading instruments calibrated in rms voltage values. On the forward (up scale) half cycle, it is evident that the instrument

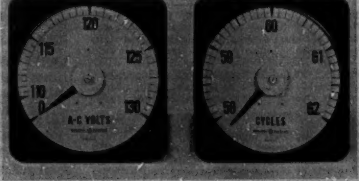

Fig. 7. Switchboard instruments for limited-range measurement of voltage and frequency using Zener diodes

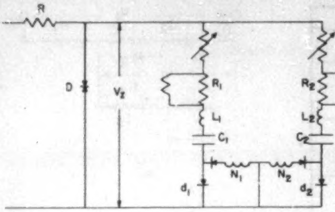

Fig. 8 (left). A diode circuit for the measurement of frequency

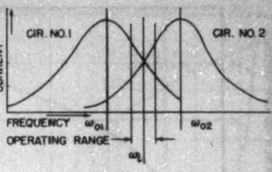
Fig. 9 (right). Current-frequency relationship in the 2-series RLC circuits



will respond to the average value of the potential V_0, and in the absence of other effects would duplicate the errors of an averaging instrument. On the reverse half cycle, the instrument responds to the average value of the Zener voltage, and the general effect of the low harmonics is to increase or reduce the Zener average at a greater rate than the forward voltage is changed. Exact cancellation of the wave-form error is, however, obviously impracticable for more than one harmonic, and the Zener voltage was selected to minimize the effect of the third harmonic. Using a ratio of Zener-to-peak voltage of 0.15, the maximum error due to 10% of third harmonic was +0.8% of reading as compared to an error of −3.8% for an average reading instrument. Additionally, filtering will further minimize the wave-form effect but with adverse effects on the frequency characteristic. For this reason, filtering should be limited to applications where frequency is precisely maintained and where the harmonic content is large and variable.

Frequency Measurement

Since frequency meters are inherently limited range instruments, it was not expected that Zener diodes would directly contribute to sensitivity. They are quite useful, however, in their normal function of voltage stabilization, which is essential to meeting ASA accuracy limits when a differential output from the impedance network is used to operate the indicator or recorder.

Table I. Change in Harmonic Content with Voltage

Input Volts, Rms	Output				
		Third Harmonic		Fifth Harmonic	
	Volts	Volts	%	Volts	%
108	24.0	6.9	29	3.1	13
120	24.3	7.2	30	3.5	14.5
132	24.6	7.4	29.6	3.7	14.8

Conditions:
60-cycle sine-wave input
28.8-volt (average) flat-topped output at 16.6 (average) milliamperes
Two sets of three 8-volt diodes

Frequency meters pose a special problem in respect to voltage stabilization, since most stabilizers are sensitive to both wave form and frequency of the supply. This applies especially to stabilizers which employ either saturable transformers or reactors as the voltage sensitive element. The frequency effect takes the form of: Volts out=(Frequency)^n where n is between 1 and 2. The effect can be calibrated out, but also must be designed out since it introduces an undesirable skew in the scale distribution. However, in the author's experimental work with two forms of saturable transformers, it was observed that the harmonic content of the output increased with the voltage even though the average value of the output voltage remained constant. Since the frequency meter necessarily includes two circuits whose relative admittance to these harmonics is not the same, the frequency meter showed a positive variation with increasing voltage, even at midscale frequencies. After brief experiments with filters, it was concluded that such stabilization was inconsistent with our objectives of simplicity and flexibility of application. In particular, it would be necessary to develop stabilizers for each required voltage and frequency range.

Attention was then turned to Zener-diode stabilization using the circuit shown in Fig. 8. Here the incoming voltage wave is clipped to a constant average voltage V_z by the back-to-back group of diodes D. Both the voltage and current of the frequency meter must be held to a minimum to limit the number of diodes used. The output voltage wave is trapezoidal in shape, having about 30% third- and 15% fifth-harmonic content. However, the harmonic content does not change appreciably with voltage as given by the figures in Table I.

A change of ±10% in primary voltage causes a change of $\pm 1^1/_4$% in secondary fundamental voltage, with a calculated voltage error of 0.6% of span, as compared to a specified maximum of 1.5% of span. The change in harmonic content of a typical voltage stabilizing transformer is about five times the preceding values.

The stabilized voltage V_z is then applied to two RLC circuits in parallel, as shown in Fig. 8. These circuits filter out most of the harmonic content, a typical value being 6.9% third and 2% fifth for circuit No. 2. It is not the harmonic content, per se, but change in harmonic content that causes abnormal voltage error with saturable-type stabilizers.

The frequency-current characteristics of the RLC circuits are shown in Fig. 9. Circuit no. 1 is resonant below, and circuit no. 2 is resonant above the operating range with approximate linearity of the differential current in this range. This

Table II. Constants of Type AB-18 120-Volt 58–62-Cycle Frequency Meter

		ASA Specifications	Type AB-18
Rating; volts		120	120

* Effect of 65 C is not included in ASA specifications. The Navy specification tolerance is used instead.

current is measured by the half-wave differential milliammeter shown as coils N_1 and N_2 in Fig. 8. The remaining diodes, d_1 and d_2, are included only to allow normal response of the resonant circuits to alternating current, and have no further influence on the measurement. The *RLC* circuits are computed by conventional methods to obtain the desired input-output characteristics, for the required voltage and frequency span.

Conclusions

The Zener diode is a component of significant value in measurement circuits, when as either a voltage reference or as a voltage stabilizer. One example of its use as a voltage reference is the expanded scale, or limited-range voltmeter, in which the indicator essentially measures the difference between the Zener voltage and an appropriate fraction of the unknown voltage. The basic indicator accuracy is then applicable to this voltage difference instead of the entire voltage, thus enhancing the accuracy of the total measurement. By appropriate circuitry, this basic arrangement may be extended to alternating voltage and direct or alternating current. With temperature compensation, the accuracy of such arrangements approaches the value (indicator accuracy x span), provided that the wave-form error, inherent in the rectification process, is eliminated by calibration or adjustment.

Additionally, the Zener diode is an excellent voltage stabilizer for short-span frequency meters. Here, the harmonics introduced by the clipping action of the diode are substantially filtered out by the resonant circuits, and more importantly, the harmonic content does not change appreciably with current. The constants of a 120-volt 58–62-cycle instrument in comparison to ASA specifications are given in Table II. Since the major ASA tolerances are given in per cent of span and were written when 8- to 10-cycle spans were common in 60-cycle instruments, the specifications may be unnecessarily exacting for a 58–62-cycle range. They can, however, be met with the diode circuit. Experiments have also shown that a 59–61-cycle span is practicable but probably unnecessary with the liberal scale lengths and chart widths used on switchboard instruments. It also follows that this circuit consisting of voltage stabilization, transduction, measurement (abbreviated the STM circuit) is adaptable to any measurement in which impedance change can be used as the measurement parameter.

A Generalization of the Calculus of Finite Differences to Nonuniformly Spaced Variables

GABRIEL KRON
FELLOW AIEE

Synopsis: In the conventional calculus of finite differences the *n* sets of *k* independent variables $x_{(1)}^{\alpha}, x_{(2)}^{\alpha} \ldots x_{(k)}^{\alpha}$ are assumed uniformly spaced along each of the *k* axes of a rectangular frame. Occasionally nonuniform spacings are also assumed, but only along one dimension.

In the proposed calculus the *n* set of *k* independent variables (representing, say, experimental data) are considered as *n* arbitrary points scattered around in a *k*-dimensional Euclidean space. These points are used as anchors for the construction of a new type of reference frame. The frame consists of a network of branches connecting neighboring points; plus a network of planes connecting neighboring branches; plus a network of cubes connecting neighboring planes; and so on, until a network of *k*-dimensional cubes (*k*-spaces) connect the neighboring $k-1$ dimensional cubes. These *k* networks are also interlinked with each other, forming boundaries of one another.

The dependent variables y_α (one or more sets) and their differences of various orders are no longer considered as electric currents and voltages, but rather as electromagnetic waves propagating across the complex of interconnected 0-, 1-, 2-. . . to *k*-dimensional networks, leaving in their wake electric charges and magnetic poles. These generalized waves obey the generalized Stokes' theorems of combinatorial topology. By subjecting the *k* underlying networks, as well as the superimposed electromagnetic waves, to various manipulations so familiar to electrical and electronic engineers, much of the ingredients of a new nonuniform calculus are available for the study of a wide variety of problems in advanced numerical analysis, statistics, and physics.

Of course, the paper submits only a mechanism, not mathematical proofs of the mechanism. The proofs lie in the physical background of the concepts. This paper extends the complete algebraic diagrams developed for a linear graph, to show the tensorial concepts and transformation theory to be used in connection with the entire complex of *k* networks. A proposed path for the electromagnetic waves, to be assumed in simple *k*-dimensional interpolation problems by Newton's formula, is also shown. Eventual solution of extensive problems in nonuniform *k*-dimensional curve-fitting, also smoothing of experimental data, among other things, is anticipated, with the aid of the nonuniform wave-model and the method of tearing.

Physical Problems

PHYSICAL BACKGROUND FOR SOLVING DIFFERENTIAL EQUATIONS

In solving partial differential equations of physical problems (say when analyzing the stresses of an elastic body), it is customary to replace the physical structure by a set of uniformly spaced points in space, at $\Delta x_{(1)}^{\alpha}$, $\Delta x_{(2)}^{\alpha} \ldots$ distance apart, Fig. 1(A). These points define the independent variables $x_{(1)}^{\alpha}$, $x_{(2)}^{\alpha}$, $x_{(3)}^{\alpha}$. Then to each point a dependent variable y_α is assigned, as well as a succession of first-, second-, third-, etc. differences Δy_α, $\Delta^2 y_\alpha$, $\Delta^3 y_\alpha \ldots$. As a result of discretization, a set of algebraic equations (linear or nonlinear) are generated and solved.

follows a different approach to discretization. He also replaces the physical structure by a set of spatial points. Afterward, however, he interconnects the neighboring points by a set of branches, Fig. 1(B), in which electric currents are assumed to flow. The pattern of branches, and the impedances assigned to them, depend on the nature of the differential equations. The currents and voltages, superimposed upon the branches, represent the dependent variables, their first (and sometimes second) differences, and the divided differences. Mathematicians usually introduce differences Δy_α with order much higher than there are differentials dy_α in the given equations (in order to introduce better accuracy). However, the author never indulges in that practice. He reasons that there are no physical bases behind any differential coefficients which are not included in the given differential equations themselves.

The emphasis is on the word "physical," which also implies "geometrical" or other conceptually-existing model. The author always differentiates between mathematical manipulations and physical manipulations. He aims at introducing into the solution of his problems (if an introduction is possible), only such mathematical manipulations as have a physical (or geometrical) interpretation. Thus he always attempts to set up a physical model for the problem at hand, in the form of an electric circuit, before starting its solution.

ENDOWING EQUATIONS WITH AN UNDERLYING "STRUCTURE"

The physical models used systematically by the author offer certain advantages that purely mathematical equations do not imply. For instance, in partial differential equations the model corresponds to the physical picture that mathematicians have established for a finite material block $\Delta x\Delta y\Delta z$, before going to the limit to establish the partial differential equations. As another example, the electric-circuit models of a mechanical structure give easy access to all the internal stresses and strains that reside in the system.

Moreover, because of the availability of a model, it is comparatively simple to solve large physical systems in small installments by tearing the system apart into an arbitrary number of small structures and solving each separately. The constraint forces appearing at the points of tear are available outright by inspection, without any search.

In general it may be said that the purpose of an electric-circuit model is to endow the formless, amorphous equations (the "algebraic structure"), with an underlying "topological structure." The latter keeps the algebra within proper

bounds and directs its course of manipulation and solution.

Of course, the establishment of a structure or model for a physical system is comparatively simple. Often the system itself is its own model (as in electrical networks). In mechanical and dynamical systems, however, it is necessary to endow the underlying topological structure with a superimposed tensor structure in place of a scalar one, before the process of solution begins.

In economic problems the underlying structure is usually hardly discernible, or is entirely absent. It may thus be said that the primary purpose of the theories of economics, of statistics (and of numerical analysis) is to take a given set of amorphous, uncoordinated data and to "breathe life" into them; to endow the numbers with some organization, some "structure." This present paper is an attempt to do just that; namely to set up an underlying topological structure, as well as a superimposed algebraic structure, for a set of arbitrary numbers. The only assumption made about the given set of numbers, is that they belong to an unknown function that possesses derivatives of appropriately high orders at the given points.

ELECTRIC-CIRCUIT MODEL OF THE FIELD EQUATIONS OF MAXWELL

One frequently heard objection against an electric-circuit model of a physical system is that the electric circuit is a linear graph only; an electric circuit cannot represent geometrical planes and cubes with which actual physical systems abound. Since the development to be represented in this paper is based just upon these allegedly missing elements, it becomes necessary to call attention to certain properties of electric circuits so often overlooked.

It is well known that Maxwell, Lord Kelvin, and many other physicists have attempted for many years to establish a mechanical model for the electromagnetic field. All trials ended in failure, because gyroscopes do not behave as displacement currents do. However, by using capacitors, inductors, and ideal transformers, all stationary elements, the author succeeded in establishing a correct (though discrete) electric-circuit model for the electromagnetic field.[4–7] The model shown in Fig. 2 is physically realizable and it has been used to solve steady-state wave-guide and other problems (in two dimensions) by many independent workers. The model is also correct for 3-dimensional transient wave-propagation studies.

In the model of Fig. 2 the copper wires carrying the electric currents do form a linear graph; but the magnetic flux lines linking the wires do not; nor do the electrostatic flux-lines passing between the plates of a condenser. The flux lines pass through planes (bounded by wires), and also pass through cubes (bounded by planes and wires). The cubes may or may not be filled with electric charges and magnetic poles.

The most gratifying, and of course crucial, feature of the model is the appearance, in the ideal transformers, of arbitrary number of magnetic flux lines to represent the arbitrary nature of the magnetic vector-potential *A*. The numbers of these flux lines depend on the entire history of the network model.

The *k*-dimensional models of the present paper are based upon the circuit of Fig. 2. First the latter circuit is generalized from orthogonal curvilinear reference frames to arbitrary reference frames having nonuniformly spaced points, as shown in Fig. 3. The step from three to an arbitrary number of *k*-dimensions requires only geometrical and mathematical extensions and manipulations.

It is well known that Maxwell's field equations satisfy Stokes' theorem (multiple integral relations between divergences and curls of tensors and tensor-densities of various valence). A topological complex of networks, as well as the algebraic structure superimposed upon the underlying structure, also must satisfy Stokes' theorem generalized to *k* dimensions.[8,9] Thus the author feels confident that by allowing his networks and the electromagnetic waves superimposed upon his networks to follow the generalizations for the field equations of Maxwell, both the networks and the waves automatically satisfy also Stokes' theorem.

Of course, in practical computational work the model networks need not be established; not even on paper. A correct code can replace all paper models in any number of dimensions. As a matter of fact, advanced texts on combinatorial topology never show even a linear graph, much less a higher-dimensional model.

Numerical Analysis

INDEPENDENT VARIABLES

Translating the given physical background into the language of numerical analysis, let a set of tabular arguments x^{α} (one set of independent variables) be given, Fig. 4(A). If the arguments are plotted along the x axis, the first differences x_2-x_1 or x_3-x_2 may be visualized as the geometrical concept of distance. But the customary second differences x_3-x_1 or x_4-x_2 cannot be visualized geometrically. By logic, the

second differences of the independent variables ought to represent areas, if the first differences represent distances. But in Fig. 4(A) they do not. At best, the second differences approximate an area by means of the greatest distance, defined by three neighboring points that lie in one dimension.

With two sets of independent variables $x_{(1)}^{\alpha}$ and $x_{(2)}^{\alpha}$, Fig. 4(B), two points can define a distance and three points an area. But no volumes can be defined. With three sets of independent variables, Fig. 5, lines, planes (triangles), and cubes (tetrahedrons) can be introduced with the aid of two, three, or four neighboring points.

Thus when k independent variables are given, each with n elements, they will be considered as n points in a k-dimensional Euclidean space. The distance between any two points (say 3 and 5) is

$$d_{35}=[(x_{(3)}^{1}-x_{(5)}^{1})^2+(x_{(3)}^{2}-x_{(5)}^{2})^2+\ldots(x_{(3)}^{k}-x_{(5)}^{k})^2]^{1/2} \quad (1)$$

Table I. Given Dependent and Independent Variables

y_3	$x_{(1)}^{3}$	$x_{(2)}^{3}$		$x_{(k)}^{3}$
....	....	....	....	....
y_n	$x_{(1)}^{n}$	$x_{(2)}^{n}$		$x_{(k)}^{n}$

To establish a linear reference frame, every point is connected with about $2k$ neighboring points, whose distances are shortest. Points at "corners" are connected to only about k neighboring points; those along edges to about $k+1$ points, and so on. The aim is to erect a linear reference frame so that the branches emanating from each point should span the entire k dimensional space.

Similarly, a planar reference frame is rigged up with sets of three points (triangles) covering minimal areas. Next the k-dimensional space is spanned with tetrahedrons having minimal volumes, and so on. The manner of assuming the reference spaces depends on the accuracy of calculations wanted. For instance, a plane may be defined by more than three points, etc. The assumption of a variety of reference frames is analogous to the various types of differences (forward, central, etc.) that are assumed in conventional studies.

The square of the distances, areas, and volumes will be assigned as impedances (inverse admittances, or rather, permeabilities μ or ϵ) associated with each network element. In the interconnected structure (called "polyhedron" or "polytope") each even-dimensional network will be constructed of magnetic material and each odd-dimensional network will be constructed of dielectric material.

With k independent variables, it is possible to build up higher than kth differences. But in that case the points can not define larger than k-dimensional volumes. With $k=1$ all results become, then, identical to those of the conventional calculus of finite differences.

To establish divided differences and to interpolate, it will be sufficient to assume that the polyhedron is torn dimensionwise into k isolated networks. Each q-dimensional network itself is, however, left interconnected.

Dependent Variables

Let now a set of dependent variables y_α also exist, in addition to the n sets of k independent variables $x_{(k)}^{\alpha}$, shown in Table I. (These variables can be assumed to be complex numbers, but for the sake of better visualization, they are real.) The variables originate, say, in connection with a set of observations, or experiments.

The dependent variables y_α will be assumed to be represented by magnetic poles. The poles produce B_O magnetic flux lines, placed on their respective points. Because the flux-lines will be assumed to undergo sinusoidal variations in time (say 60 cycles), the y_α also represent generated voltages

$$y_\alpha=B_O=dB_O/dt \quad \textbf{(2A)}$$

that appear upon each junction-point of the complex. Thus at the end-points (boundaries or junction-pairs) of each branch there appears a difference of potential

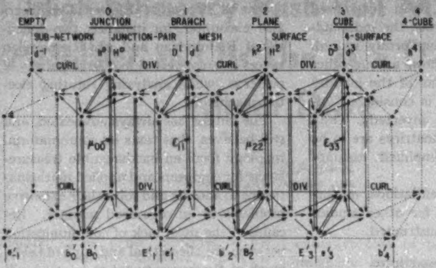

Fig. 8. Algebraic diagram of a sequence of networks

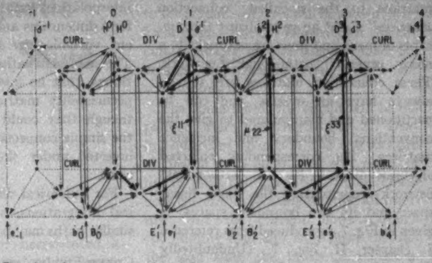

Fig. 9. A sequence of transformation steps to generalize Newton's interpolation formula

$$E_1 = \text{div}\ \dot{B}_O \qquad (2B)$$

(This first step may also be considered by assuming an absolute potential V at each point, $V = y_\alpha$. Then across each junction-pair there appears the difference of potential

$$E_1 = \text{grad}\ V\,) \qquad (2C)$$

Since each linear branch has a dielectric permeability ϵ^{11} proportional to its inverse (length)^2, an electrostatic flux-line D^1 flows in each branch

$$D^1 = \epsilon^{11} E_1 \qquad (2D)$$

Thus the total stored electrostatic energy in the entire linear network is equal to the sum-of-squares of all first-order divided differences

$$U_{(1)} = \Sigma E_1 \epsilon^{11} E_1 = \Sigma D^1 (\epsilon^{11})^{-1} D^1 = \left(\frac{y_n - y_{n-1}}{x_n - x_{n-1}}\right)^2 \qquad (2E)$$

(The "sum-of-squares" concept in statistics is as basic as the "total-stored-energy" concept is in physics.)

By Maxwell's electromagnetic field equations it is known that a sinusoidal $dD/dt = \dot{D}$ is equivalent to a displacement current, and that such a current also produces a magnetomotive force H by the relation

$$\dot{D}^1 = \text{curl}\ H^2 \qquad (2F)$$

However, this H^2 appears upon the planes and not upon the linear branches. Since the planes are assumed to be constructed of magnetic materials having a permeability μ^{22}, which is proportional to the inverse (area)^2, a magnetic flux B_2 appears across the planes

$$B_2 = \mu_{22} H^2 \qquad (2G)$$

where μ_{22} is the inverse of μ^{22}. The total stored magnetic energy in all second-order divided differences.

$$U_{(2)} = \Sigma H^2 \mu_{22} H^2 = \Sigma B_2 (\mu_{22})^{-1} B_2 \qquad (2H)$$

Up to this point one cycle of the electromagnetic wave-propagation has been generated. The production and propagation of E_3, D^3, then H^4, B_4, etc. continues, until the kth dimension is reached. In each network surplus electric charges or magnetic poles accumulate during propagation which may or may not influence the further course of propagation, depending upon the problem at hand. Also the total stored energy in each network is equal at all times to the sum-of-squares of the respective divided differences.

Ideological Graphs

ALGEBRAIC DIAGRAMS

The "algebraic diagram" of Fig. 6 (reproduced from reference 3) shows all transformation tensors C, A and all impedance tensors Z, Y associated with the study of a system, as well as it shows all relations between these tensors. In particular, Fig. 6(A):

1. The dots represent the spaces of currents (upper row) and voltages (lower row). Each dot itself represents an entire network (linear, planar, cubic, etc. network).
2. The horizontal arrows represent the "incidence" matrices M. They show how the basic spaces are related to each other.
3. The vertical arrows represent the impedance and admittance matrices Z and Y associated with each network.
4. Fig. 6(B) shows by slant arrows the manner of forming the boundary spaces associated with the basic spaces. These inter-relations are expressed by matrices C and A, called "boundary operators."

The vertical Z and Y matrices are square and usually non-singular. (They usually have an inverse.) The transformation matrices contain +1, −1 and 0 as their elements, and are characterized the fact that they are rectangular, not square, and thus they have no inverse.

The product of two matrices is represented on the algebraic diagram by the sum of two arrows. The sum is either a third arrow or zero. Thus from Fig. 6(B) (going against the arrows by convention)

$$C^1 A_t^2 = M_{12}$$

$$A_t^3 C^2 = 0 \qquad (3)$$

Moreover the currents are represented on the algebraic diagram by short vertical arrows (not shown on Fig. 6, only on Figs. 8 and 9) entering each space of the upper set of dots. The voltages are similarly represented by short vertical arrows entering the lower set of dots. Thus the algebraic diagram supplies visually all "dead" and "live" tensors associated with the system, and also all possible algebraic manipulations with the tensors. The analysis of a problem consists thereby of picking out, from all possible routes of procedure, the most suitable ones that require the minimum of computations.

ENTER ENGINEERING

As has often been the case in the past, theoretical mathematicians are not interested primarily in solving practical problems. They erect an artistic and self-contained theoretial structure and leave it to the engineers and physicists to make it workable in practice. Similarly the incidence matrices and boundary operators of combinatorial topology, because of their rectangular form, do not allow a free unrestricted passage back and forth between the various spaces. However, in all practical applications it is an absolute necessity to travel to and fro freely in all directions: from currents to voltages; from the equations of state to the equations of solution; from one dimension to another dimension; and so on.

In order to acquire such a freedom of movements, the author has generalized the concepts of incidence and boundary matrices to the so-called "connection matrices" C_β^{α}[2,3] by generalizing the concepts of mesh and junction networks to a more general "orthogonal" network. These connection matrices are square, always have an inverse, and can be partitioned and manipulated to give the conventional boundary and incidence matrices. The corresponding enlarged algebraic diagram for one "orthogonal" network (representing the single linear space and its two boundary spaces) is given in Fig. 7, reproduced from reference 3. chapter II, Fig. 7. (Undoubtedly these nonsingular transformation matrices may have already been recognized by topologists, and are hidden somewhere among their esoteric symbolism and terminology.)

Now, a sequence of such complete algebraic diagrams, given in Fig. 8, shows all the available tensorial concepts and all the possible routes of procedure, for the numerical solution of problems under consideration. The diagram can be further enlarged and generalized, as it has often been done in reference 3 for the linear portion. (There are also other cross-paths not shown on the diagram.)

Practical Applications

Interpolation

The algebraic diagram also enables the engineer to plan his passage through the labyrinth of spaces with the least amount of numerical computations for any particular problem or assumptions. Thus the algebraic diagram serves as a "thinking-graph."

For example, the heavily-drawn arrows on Fig. 9 show one of the several possible steps that can be taken in using Newton's interpolation formula, when generalized for k dimensions and when the independent variables are nonuniformly spaced. The assumed paths show, among other things, that no inversion of the induced permeability matrices is considered (although they could be inverted). Only the simple connection matrices are to be inverted under the simplified assumptions.

For numerical differentiations, numerical integrations, and for other studies similar paths may be constructed.

Curve-Fitting and Smoothing

It should be noted that during the simple wave-propagation assumed for interpolation, numerical differentiation, and integration, etc., purposes, no feedback was assumed to exist among the waves. As soon as more involved statistical or physical problems are investigated (such as curve-fitting, or smoothing), the waves in the various spaces begin to react upon each other and thereby the induced permeability matrices must be inverted, either singly or simultaneously.

The author and his associates anticipate the appearance of linear and nonlinear equations, boundary value and eigenvalue problems, as well as optimizations of various types, in which all spaces influence the answer to various degrees. In the solution of such extensive problems the method of tearing[3] promises to become a useful tool.

Curved Spaces

The Euclidean planes and cubes of higher dimensions are, of course, only the simplest types of building blocks that form a complex. Combinatorial topology assumes almost any imaginable curved spaces as elements. Electrical engineers also encounter, for instance, two-dimensional Riemannian and non-Riemannian spaces interconnected in a large variety of patterns, while analyzing rotating electric machinery.

The author has always advocated, and still believes, that texts on combinatorial topology form an inexhaustible treasure-house for engineers and applied mathematicians to analyze and solve their extensive problems in an organized manner. Because of the utter lack of communication between the theoretical and applied fields, much of the concepts yet to be used will have to be rediscovered, processed, and put to practical use by the interested engineers themselves.

High-Efficiency Push-Pull Magnetic Amplifier and Its Use as a D-C Shunt Motor Drive

C. L. BOYAJIAN
ASSOCIATE MEMBER AIEE

Synopsis: This paper describes a d-c push-pull magnetic amplifier which is used to drive a d-c shunt motor. A circuit called the high-efficiency push-pull magnetic amplifier circuit was used successfully to drive a 1/20-horsepower d-c shunt motor.[1]

This circuit has made the application of magnetic amplifiers to driving d-c motors in reversible operation practical.

The general operating characteristics of this circuit are discussed and actual data presented. The problems associated with driving a d-c motor load and the factors influencing the design of the circuit are discussed. The results achieved in using the high-efficiency circuit in an actual application are presented.

A COMMONLY used d-c push-pull full-wave magnetic amplifier circuit is shown in Fig. 1. This circuit has a maximum theoretical efficiency of 17%. This circuit has a maximum theoretical efficiency of 17%. This efficiency is based on the assumption that the internal impedance of the amplifier circuit as seen from the load is negligible and that the load resistance is equal to the $\sqrt{2}$ times the resistance of one of the dummy load resistors.

The large power loss associated with this circuit is undesirable of course. This becomes of greater concern as the power level of the application increases.

A different magnetic amplifier circuit was invented in 1952 by B. D. Bedford of the General Electric Company. This amplifier circuit has a maximum theoretical efficiency of 50% as compared to the 17% efficiency of the circuit of Fig. 1. The circuit was called the high-efficiency push-pull circuit because of its relatively higher efficiency.

Before the invention of the high-efficiency circuit, it was not too practical to drive a d-c motor in push-pull operation with a magnetic amplifier. The excessive loss of power necessitated a magnetic amplifier considerably larger than the motor load. The high-efficiency circuit makes possible an appreciable reduction in the size of a magnetic amplifier for a given load.

Basic Operating Characteristics

The high-efficiency push-pull full-wave d-c magnetic amplifier circuit is shown in Fig. 2. To understand the basic operating characteristics of the high-efficiency circuit, resistive loads will be considered first.

This circuit is the equivalent of four simple magnetic amplifier bridge circuits connected together as a bridge. The actual load is connected in the center of the bridge arrangement. The dummy load R_z is connected externally as shown. Only four cores are necessary, as shown in Fig. 2, since two gate windings are placed on one core.

The dummy load performs the following functions in the circuit.[2] First, the circuit would not work properly without it because the dummy load provides a reverse voltage across the resetting cores. The reverse voltage which prevents current flow through the diodes is necessary for the core flux to reset. Second, the dummy load impedance is necessary to help limit the standby current of the amplifier.

Maximum theoretical efficiency will result when the dummy load is made equal to the actual load. As will be shown later, for a given load, the efficiency of the circuit decreases as the dummy load decreases, approaching zero output for zero dummy load.

The operation of the circuit will be explained briefly referring to Fig. 2. During quiescent operation, the reactors are all biased to a point that will result in linear push-pull operation. The quiescent current is the same through all windings. All the current flows through the dummy load and none flows through the load since the bridge is balanced. When a d-c signal of a given polarity passes through the control windings, the cores of one reactor are turned in the "on" direction while the cores of the other reactor are turned in the "off" direction. This causes the bridge to be unbalanced, resulting in a full-wave rectified voltage of a corresponding polarity to appear across the load. A reverse signal will reverse the dummy load is always of the same polarity.

The resistors shunting the diodes provide a degenerative feedback which stabilizes the gain of the amplifier.

To show the operating characteristics of an actual high-efficiency circuit, three cases were chosen using resistance loads. The dummy load resistance was made large compared to the resistance of the other amplifier components such as the core windings, transformer windings, and diodes. The dummy load was 500 ohms for all three cases. For each case, a plot of load voltage and current, and dummy load voltage and current versus control current is presented. Only the characteristics for one polarity of signal current are shown. For the reverse polarity the load voltage and current reverse but the dummy load voltage and current are of the same polarity.

In the first case, the load resistance was made equal to the dummy load resistance. The resulting characteristics are shown in

Fig. 2. High efficiency push-pull full-wave d-c magnetic amplifier circuit

Fig. 3. From this plot, it can be seen that the maximum theoretical efficiency of 50% is approached.

In the second case, the load resistance was made five times the dummy load resistance. Fig. 4 shows that the voltages are about the same as they were in Fig. 3. The voltage across the load did not become greater than the voltage across the dummy load as might be expected.

Actually, the load voltage cannot exceed the dummy load voltage. The instant the load voltage exceeded the dummy load voltage, the complementary diodes associated with the "off" reactor would conduct. This bypasses the current from the load to the dummy load until the two voltages are equal. This is why the dummy load current is greater than the load current even in saturation, when one reactor is turned completely off. Again this shows why the dummy load is necessary.

In the third case, the load resistance is made 1/5 the dummy load resistance. Fig. 5 shows that for this condition the voltages divide approximately as the ratio of the resistance as would be expected. The current is therefore approximately the same. Initially, the load voltage has a greater slope, which is approximately the same as when the voltages divided equally as in the first and second cases. This results in the load current increasing at a rate that would make it exceed the dummy load current. However, this is not possible since any current that passes through the load must also pass through the dummy load. The dummy load restricts the level of load current resulting in the two currents being approximately the same. In some applications, a nonlinear gain characteristics such as this is undesirable.

The data shown in Figs. 4 and 5 show that the efficiency of this circuit decreases whether the load is greater or less than the dummy load.

The data in Fig. 6 show the push-pull operation of the circuit. These data will be used to compare the results achieved when the motor load is used.

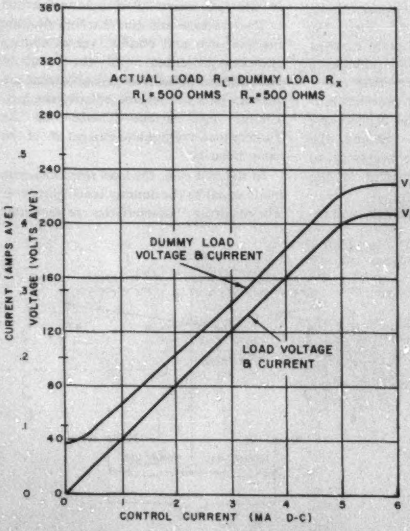

Fig. 3 (left) and Fig. 4 (below). Amplifier voltage and current characteristics for resistance loads

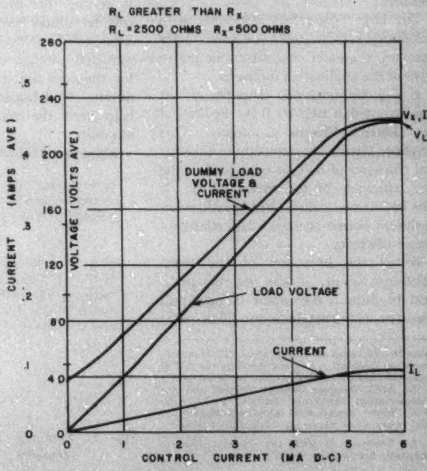

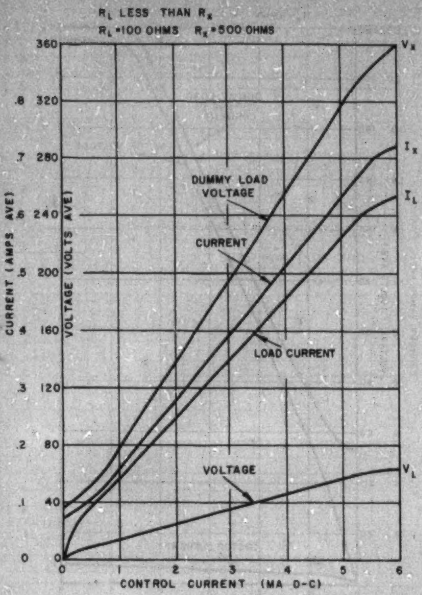

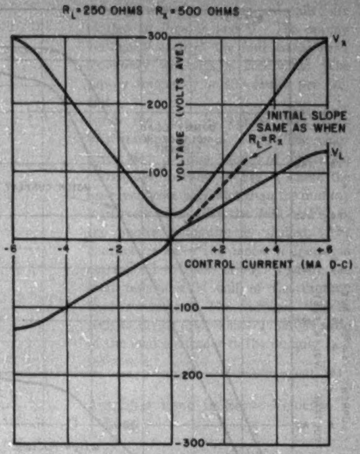

Fig. 5 (left). Amplifier voltage and current characteristics for resistance loads

Fig. 6 (above). Amplifier push-pull voltage characteristics

A summary of the characteristics of this circuit as shown in Figs. 3, 4, and 5 is as follows:

1. V_L can not exceed V_x.
2. I_L can not exceed I_x.
3. When $R_L > R_x$, the approximate characteristics are, $V_L = V_x$ and $\frac{I_L}{I_X} = \frac{R_X}{R_L}$.
4. When $R_L < R_X$, the approximate characteristics are $I_L = I_X$ and $\frac{V_L}{V_X} = \frac{R_L}{R_X}$.
5. Maximum efficiency is achieved when $R_L = R_X$.

Motor Load

When the high-efficiency circuit is used to drive a d-c shunt motor, there are a number of factors to be considered. For this discussion, the motor field is separately excited so that the amplifier load is the armature of the motor.

The effective impedance of the motor varies considerably for different modes of operation. These modes are, the steady state conditions of stalled motor and motor running at a constant velocity, and the transient conditions of acceleration and deceleration. This presents the problem of matching the dummy load to the motor load for highest efficiency or deciding what dummy load will result in the best over-all operation for a particular application.

When the motor is stalled, the armature presents a resistive load to the d-c output of the amplifier. When the motor is running at a constant velocity with no load, the armature presents a high effective-load impedance, relative to the stalled resistance, due to the counter electromotive force voltage generated by the motor armature. This effective impedance was approximately 50 times greater than the stalled armature resistance for the motor employed.

When load is applied to the running motor, the effective impedance decreases. Also, transient operation of the motor presents varying impedances.

Because of these variations in the effective motor impedance, it would be impractical to try to design a dummy load that would vary as the motor load. The simplest solution is to choose a value of resistance for the dummy load that will result in the best over-all operation for the particular application involved.

The following are some of the factors that would influence the choice of the dummy load resistance:

1. The maximum stalled torque required.
2. The acceleration required.
3. The power dissipated in the dummy load resistor.
4. The duty cycle of the motor.

If the dummy load resistance is made equal to the stalled-motor armature-terminal resistance, maximum stalled current would flow resulting in maximum stalled torque and maximum acceleration for a given supply voltage. The disadvantage of this condition is that when the motor is running with little or no load, the efficiency of the amplifier drops off considerably. This is because the armature current is very low while the dummy load current remains about the same as for the stalled condition since the voltage across it remains the same. This results in a large loss of power which is undesirable.

For this reason, it is desirable to increase the dummy load resistance. The

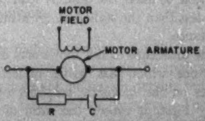

Fig. 7. D-c shunt motor with resistance-capacitance network across armature terminals. Motor field separately excited

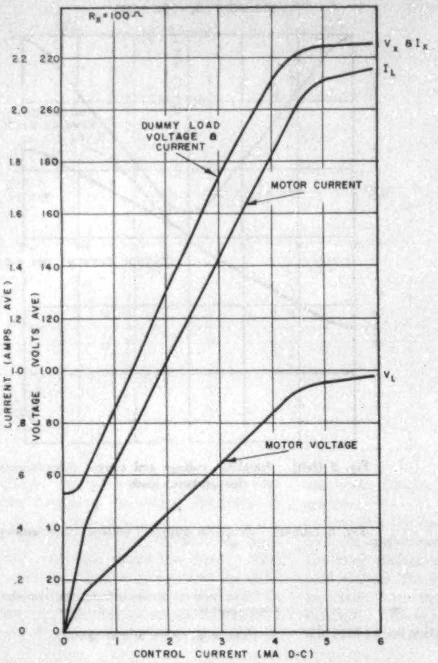

Fig. 8. **Amplifier characteristics with stalled motor load**

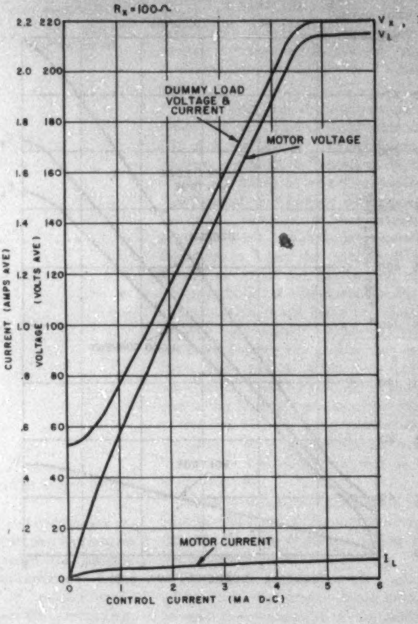

Fig. 9. **Amplifier characteristics with running motor load (no load on motor)**

amount it should be increased depends on how much of the time the motor would be running, especially at light loads, and also on the maximum torque requirements. As the dummy load resistance is increased, the maximum available torque is decreased since the load current is limited by the dummy load resistance as shown in Fig. 5. Increasing the dummy load resistance will decrease the quiescent power dissipation which is desirable. The nonlinear load characteristic shown in Fig. 5 may or may not be tolerated, depending on the application.

Under no circumstances would it be desirable to make the dummy load resistance less than the stalled motor armature resistance.

The armature of the motor has an inductance which has some undesirable effects on the magnetic amplifier operation. First, it causes the ratio of load voltage to dummy load voltage, under stalled conditions, to be lower than it would be if the inductance was zero. Also, the magnetic amplifier investigated had a slight tendency to snap and had a discontinuous gain characteristic.[1,2]

These inductive effects were removed by the addition of a series R-C network across the motor armature terminals as shown in Fig. 7. The network improved the ratio of load voltage to dummy load voltage under stalled conditions to approximately the expected value as shown in Fig. 8. The network also filtered the ripple current through the motor armature resulting in the quiet operation of the motor.

The other factor to be considered is the effect that the magnetic amplifier has on the response of the motor. The motor response depends on the effective impedance of the amplifier as seen from the motor armature terminals. In calculating the motor inertia time constant $T = JR/K_tK_e$, the R becomes the sum of the motor terminal resistance and the effective output resistance of the magnetic amplifier. In the actual application to be discussed next, the motor time constant was approximately doubled.

Actual Data of Amplifier Driving a Motor Load

A presentation of data taken with the magnetic amplifier driving a d-c shunt motor will show the results that can be achieved. The circuit of Fig. 2 was used with the motor load plus the R-C network as shown in Fig. 7. The amplifier is the same as the one used to take these data for Figs. 3–6. The d-c field of the motor was separately excited.

The motor has a continuous rating of 1/20 horsepower at 4,000 rpm and 115 volts. It can deliver a maximum torque output of 50 inch-ounces with an armature current of 2 amperes. The armature terminal resistance is approximately 45 ohms.

Although the continuous rating of the motor is 1/20th horsepower, the amplifier is capable of driving the motor to deliver a peak power output of 1/7th horsepower.

The application for which this circuit was developed has the following requirements. The amplifier must be able to maintain torque saturation of the motor

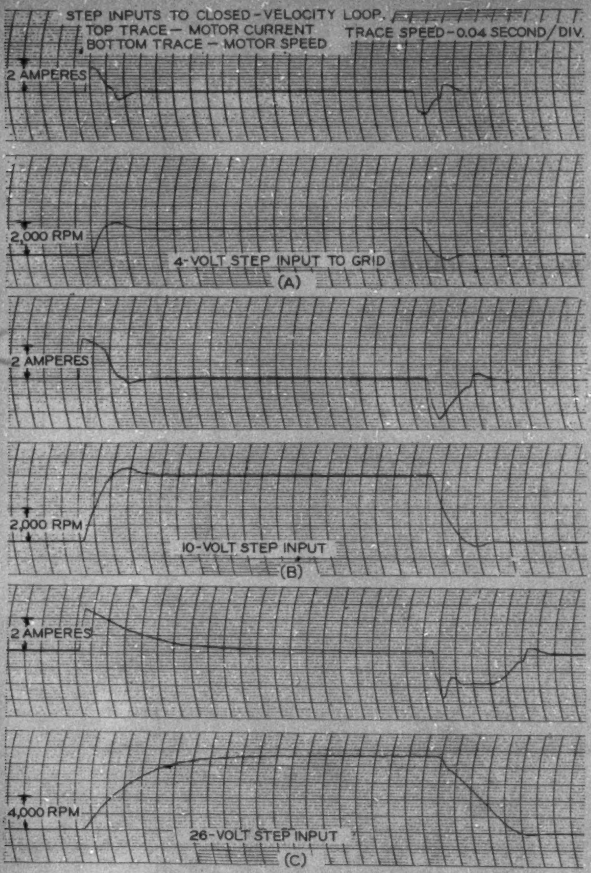

Fig. 10. Transient response of closed velocity servo loop showing motor armature current and motor speed simultaneously against time

until it reaches rated speed to achieve maximum acceleration with step inputs. In other words, the amplifier must deliver 2 amperes to the motor armature until rated motor speed is reached when a large input signal is applied suddenly to the amplifier. The motor during another mode of operation, accelerates and decelerates 50% of the time and runs at a constant velocity with a light load 50% of the time. Also, it is necessary to keep the power dissipation at a minimum because it is to be used in an air-borne application.

Although the motor is to run at a constant velocity with a light load 50% of the time, it was necessary to keep the resistance of the dummy load low to be able to achieve the required high acceleration requirements for step inputs. A dummy load resistance of 100 ohms was used as a compromise between the desired 45 ohms for high acceleration current and the high resistance desired for constant velocity operation, which is about 2,500 ohms.

The data showing the steady state characteristics of the magnetic amplifier driving the motor running and stalled are plotted in Figs. 8 and 9. The supply voltage of each of the four transformer secondary windings is 250 volts. The supply frequency is 400 cycles per second.

For the data in Fig. 9, the motor was running with no load. The characteristics of this mode of operation correspond to those of Fig. 4 where the load resistance is greater than the dummy load resistance. For the data of Fig. 8, the motor armature is stalled. The characteristics of this mode of operation correspond to those of Fig. 6 where the load resistance is half of the dummy load resistance. The voltages can be seen to divide approximately as the ratio of the load resistance to the dummy load resistance.

Amplifier Used in Servo-Velocity Loop

The particular amplifier and motor mentioned were used as part of a servo-velocity loop. The magnetic amplifier was driven by a d-c push-pull electronic driver stage. The resulting time constant of the magnetic amplifier was approximately 0.005 second. The inertia time constant of the motor when driven by the magnetic amplifier was 0.08 second and the armature inductive time constant was approximately 0.001 second. With the proper amount of velocity feedback, the closed velocity loop frequency response was attenuated 3 decibels at an angular frequency of approximately 50 radians per second.

The recorder traces of Fig. 10 illustrate the transient response of the closed-velocity servo-loop system. The step input of Fig. 10(A) was small so as not to saturate the amplifiers. This shows the true response of the servo. The step input of Fig. 10(B) caused the magnetic amplifier to saturate initially resulting in torque saturation of the motor. The steady-state speed of 4,000 rpm is the rated speed of the motor. The step input of Fig. 10(C) resulted in the continuous saturation of the magnetic amplifier.

Conclusions

The high-efficiency push-pull magnetic amplifier circuit has made the application of magnetic amplifiers to driving reversible d-c shunt motors practical. The use of this circuit makes possible a considerable reduction in the size of the magnetic amplifier for a given application compared to the size that would be necessary if the more common push-pull circuit of Fig. 1 were used. This applies mostly to applications where the power level is such that efficiencies become quite important and the increased circuit complexity is justified by the decrease in power lost and the decrease in the size of the amplifier.

Elimination of Magnetic-Amplifier Control Circuit Inductance

D. P. CHANDLER

R. W. DOWNING
ASSOCIATE MEMBER AIEE

RESPONSE of magnetic amplifiers to signal changes is typically impeded by the necessity to change the average flux linkage of the control winding in order to obtain a different output. This inductive effect requires an elapse of time during which a voltage-time integral, proportional to the required change in average flux linkage, must be applied to the control winding before a new steady-state operating point can be reached.

In this paper the concept of magnetic amplifiers with noninductive control windings is introduced. This concept is based on proper manipulation of well-known phenomena so as to eliminate the requirement for the control-winding flux linkage to change when control and load currents are changed. The possibility of obtaining instantaneous response is demonstrated, and a practical method of approaching the condition of a noninductive control winding is presented for cases of fixed load impedances.

Nomenclature

B_0 = average (d-c) flux density
B_m = amplitude of alternating flux density
H_0 = average magnetic intensity
E = supply voltage, rms
$\mathbf{E}$ = supply voltage vector
E_{AC} = alternating voltage across magnetic-amplifier load winding, rms
$\mathbf{E}_{AC}$ = load-winding voltage vector
e_{AC} = instantaneous value of load-winding voltage
E_L = load voltage, rectified average
$\mathbf{E}_L$ = load voltage vector
e_L = instantaneous value of load voltage
I_{DC} = average control current
i_{DC} = instantaneous value of control current
I_L = load current, rectified average
i_L = instantaneous value of load current
R_L = load resistance
C_L = capacitance paralleling the load resistance
θ = carrier phase angle between load-winding voltage and load voltage
ϕ = signal phase shift between control voltage and load voltage

Vectors are shown in the illustrations by a bar over the letters.

Theory

The average flux density (B_0) in each core of a magnetic amplifier depends not only on the magnetic intensity (H_0) applied to the core but also on the amplitude (B_m) of any superimposed alternating flux density.[1,2] This dependence on B_m in a single core is illustrated in Fig. 1 for the case of materials with gradually varying **B-H** curves. Points on the sine wave of flux-density variation are projected horizontally to the **B-H** curve and then down to the corresponding time on a new time axis. The average value of the resulting curve of H over one cycle is H_0 for the given values of B_0 and B_m. This H_0 is greater than the H corresponding to the given B_0 when B_m is zero.

Expressed another way, for a given average (d-c) ampere-turns on a core (or a pair of such cores), the average value of flux linking any winding on the core is reduced if an alternating voltage is applied to a winding on the core. (The average current in a winding is fixed by the average voltage and the resistance in the winding circuit. The core cannot affect this average current.) The ability to change the average flux linkage by varying the applied alternating voltage is the tool to be used in making the control winding of a magnetic amplifier noninductive.

The quantitative relationships between B_m, H_0, B_0, and load current (I_L) have been presented by others.[3,4,5] For reference, an oscillographic example is shown in Fig. 2 taken from the magnetic amplifier described in the Appendix. Here two families of curves on the same set of co-ordinates relate the four quantities.

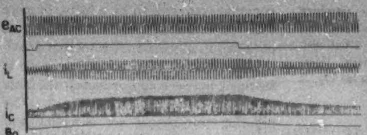

Fig. 3. Transient response of 400 cps with resistive load and conventional operation. e_{AC} is the voltage across the two load windings, i_L is the load current, i_C is the control current, and B_0 is the flux density averaged over several cycles. The extra line indicates initiation of the transient

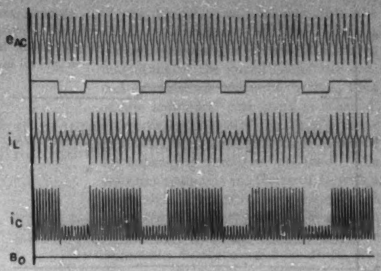

Fig. 4 (right). Transient response of 400 cps with resistive load switched synchronously with the signal in such a way as to keep B_0 constant. Symbols are same as for Fig. 3

For convenience, the alternating voltage (E_{AC}) across the load windings and the average value of control current (I_{DC}) have been used instead of B_m and H_0 to which they are respectively proportional. Note that for the major portion of the practical operating range, movement is possible along a constant B_0 curve from one set of control and load currents to another set without materially deviating from the turns-ratio law.[1,6] This law states that control ampere-turns nearly equal the load-winding rectified average ampere-turns.

To remain on a constant B_0 line it is necessary only that E_{AC} increase properly with increase load current. If this relationship is properly maintained a signal change will result in an instantaneous change in the amplitude of the load current. This is exactly true if the change occurs at an instant when the alternating flux density is zero. If the change occurs at any other time in the cycle, a slight shifting of flux densities between the cores is required, but as will be seen in the experimental results this shift takes place in an undetectably short period of time.

If E_{AC} is made to increase more rapidly, than just enough to keep B_0 constant, with increased load current, the control winding acts a negative inductance. This provides both the potentiality of derivative effects and the danger of instability.

Experimental Verification

To check the possibility of obtaining instantaneous response by making the magnetic-amplifier control winding noninductive, tests have been performed on a simple series magnetic amplifier (more completely described in the Appendix) using hypersil toroidal cores. This amplifier and its control circuit were purposely chosen to have a long transient time with a resistive load so as to make pronounced improvements possible. For all the tests, the control winding was driven from a low-impedance source, making the control winding the only effective resistance in the control circuit.

The transient response of this amplifier with resistive load and 400-cps (cycle per second) power is shown in Fig. 3. The effective time constant for these transients is approximately that which published equations would predict.[7,8]

In contrast, Fig. 4 is an oscillogram of the transient response of the same amplifier with part of the load resistance short-circuited at the same time the control voltage is increased (see the Appendix). By this means E_{AC} is increased the appropriate amount for the increase in I_L and I_{DC} so that the two steady-state conditions involved the same B_0. Admittedly this method is not practical for magnetic-amplifier applications, but it demonstrates the feasibility of making the control winding noninductive.

In order that the noninductive transient be seen in more detail, it was redone using 60-cps power; see Fig. 5. Here the instantaneous nature of the change can be seen. Transients initiated at four different phase angles of the supply power are shown in the oscillogram. Notice that the second transient occurred at an instant of zero load current, resulting in no jump, merely an instantaneous shift to a different but tangent waveform, as predicted by theory. The other three transients are more dramatic, however, actually demonstrating an instantaneous change to the new steady-state output. Superposition of portions of the two steady-state waveshapes onto the transient portions of the oscillogram indicates no detectable deviation from steady state on either side of any of the transient steps in the load current.

For still better detail, the third transient of Fig. 5 is enlarged as Fig. 6. Notice that the slope of the transient step in i_L is about the same as that for the other steps and is caused primarily by the response of the oscillograph galvanometer.

Fig. 7 is an oscillogram of the tran-

sients resulting from switching the load circuit as for Fig. 4 but without switching the signal. Here the derivative capabilities of a negative control inductance is demonstrated.

Practical Application

One practical method of increasing E_{AC} with increased load current to improve the transient response is to make the load somewhat capacitive.

To get a "feel" for the effect of capacitance across the load, assume for the moment that the load winding of the magnetic amplifier is a variable linear inductance. Then with sinusoidal supply voltage and a linear load all the voltages appearing in the load circuit are sinusoidal and may be represented by vectors. Fig. 8 is a vector diagram of such voltages for the case of a purely resistive load (dashed lines) and for a resistive-capacitive load. The supply voltage E is the same for both cases. With the resistive load, there is always a 90-degree angle between the load voltage vector $\mathbf{E}_L$ and the vector $\mathbf{E}_{AC}$ of voltage across the magnetic-amplifier load winding. This results in a semicircle as the locus of the intersection of $\mathbf{E}_L$ and $\mathbf{E}_{AC}$ for various values of the load-winding inductance (controlled by changing the magnetic - amplifier control current). When the load is made capacitive the phase angle (θ) between the inductive load winding and the load impedance is greater than 90 degrees resulting in a voltage vector diagram as shown by solid vectors. The locus of the intersection of the $\mathbf{E}_{AC}$ and $\mathbf{E}_L$ vectors is now a portion of a circle such that $\mathbf{E}$ is a chord of the circle. An examination of these diagrams shows the capability of causing E_{AC} to increase (at least over a limited range) with increase of load current by an amount determined by how capacitive the load is made.

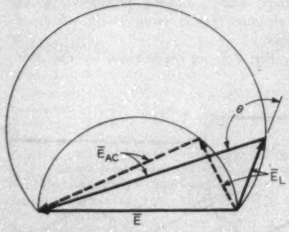

Fig. 8. Vector diagrams of load circuit voltages. E is the supply voltage, E_{AC} the voltage across the load windings, and E_L is the load voltage. The dashed lines apply for a resistive load, the solid lines for resistive-capacitive load. θ is the load impedance phase angle plus 90 degrees

For the authors' purposes, a more useful way of presenting this information is in the form of load lines[5] on the same set of co-ordinates used in Fig. 2. Fig. 9 is an oscillographic presentation of such load lines for a resistive load (lower curve) and the same load resistance paralleled by a capacitance. The capacitive load is seen to cause E_{AC} to increase with increasing load current even with the nonsinusoidal waveforms caused by the nonlinear magnetic amplifier.

By comparing Fig. 9 with Fig. 2, it is apparent that much less change in B_0 is required for a given load current change (or control current change) when the load is capacitively tuned. This is tantamount to saying the effective inductance of the control winding has been appreciably reduced. The result should be faster response to a transient. This is verified by Fig. 10, an oscillogram of the transient response resulting from capacitive tuning of the load in the amplifier circuit used to obtain Fig. 3. The tuning for Fig. 10 was limited to a value which provides no overshoot. Even so, the effective time constant was reduced by a factor of more than three. Still faster response can be obtained if an overshoot is tolerated.

The rectified average load current is swinging between approximately the same values for both Fig. 10 and Fig. 3. The differing waveshapes are deceiving and make the determination of effective time constants difficult.

Unfortunately the load lines obtainable by capacitive tuning of the load do not match exactly the constant B_0 lines for any significant variation in load current. So, from a practical standpoint, this method allows reduction of effective control-winding inductance but not elimination of it.

Application to Push-Pull Circuitry

Many applications such as driving servomotors require reversible polarity outputs from the driving amplifier. A push-pull arrangement (described in the Appendix) of two simple series-connected magnetic amplifiers is one way of fulfilling this requirement and presents some special problems worthy of consideration.

REVIEW

A review of steady-state conditions in such an amplifier is probably desirable. Because current is inductively limited in simple series magnetic amplifiers[5,6,9] it is possible to bias (by currents in control windings) both core pairs into a state of permitting about half the maximum desired load-winding current to circulate through the magnetic-amplifier load windings with no current going through the load. Then if the control currents are

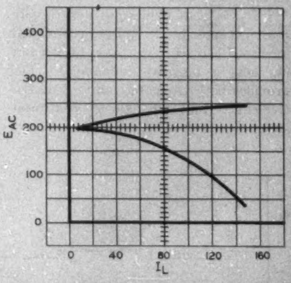

Fig. 9. Magnetic-amplifier load lines. Lower curve is for resistive load, upper for resistive-capacitive load. E_{AC} is the rms value of voltage across the load windings and I_L is the rectified average value of load current, milliamperes

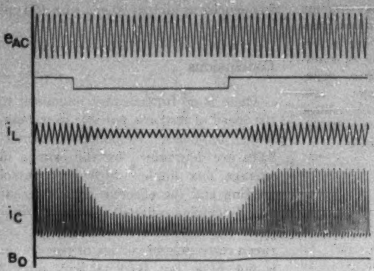

Fig. 10. Frequency response of 400 cps with resistive load tuned by parallel capacitor. Symbols are same as for Fig. 3

unbalanced, the load-winding currents are no longer balanced and their difference must flow through the load. If the control currents are unbalanced in the opposite direction, the polarity of the current through the load is reversed. Because in each of the core pairs the rectified average load circuit ampere-turns are nearly equal to the control ampere-turns,[1,4] the load current is approximately proportional to the difference in control currents and is nearly independent of the sum of the two control currents within the bounds of the operating range of the amplifier.

When a resistive load and a core material with gradually varying **B-H** curve are used, the load current and voltage are roughly 90 degrees out of phase with the supply voltage, and do not require phase shifting of power for operation of 2-phase servomotors. Fig. 11(A) is a vector diagram of the voltages in the load circuit for a given output into a resistive load. The solid vectors represent voltages when core pair 1 (whose voltage vectors carry the subscript 1) is conducting more than pair 2. The dashed vectors apply when the polarity of the output is reversed, with core pair 2 conducting more than pair 1. The curved line is an approximate locus of the end of the load voltage vector for various outputs. Notice that at all times the vector sum $(\mathbf{E}_{AC_1}+\mathbf{E}_{AC_2})$ of the voltages across the two pairs of load windings must equal the fixed total supply voltage $(\mathbf{E}_1+\mathbf{E}_2)$ regardless of the load voltage. Among other things this means that the sum of the voltage amplitudes on the load windings must increase as the load voltage increases from zero in any direction other than being in phase or 180 degrees out of phase with the supply voltage

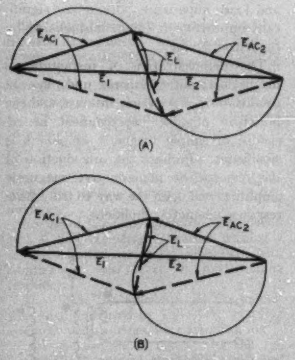

Fig. 11. Vector diagrams of push-pull load circuit voltages. $\bar{E}$ is the supply voltage, $\bar{E}_{AC}$ is the voltage across the load windings, $\bar{E}_L$ is the load voltage, and subscripts 1 and 2 refer to the two core pairs. B—Resistive-capacitive load

EFFECTS OF CAPACITIVE TUNING

Because the load current is nearly 90 degrees out of phase with the voltage across the core pair supplying the load current, the phase angle of the load voltage is controlled by the phase angle of the load impedance. In particular, making the load capacitive tilts the load voltage vector in the direction to increase the voltage across the core pair conducting the greater load circuit current and reducing the voltage across the other core pair. This effect is in the proper direction for reducing the change in B_0 from one operating point to another, so again the capacitive load is tending to improve the transient and frequency response of the amplifier. Fig. 11(B) is a voltage diagram and approximate load vector locus for a capacitively tuned load.

Load-line considerations of the push-pull circuit are complicated by the possibility of shifting the bias on both halves of the amplifier without affecting the output significantly. If the bias is changed as a function of the instantaneous magnitude of the signal (difference control current), the shape of the load lines of the individual core pairs is affected. However, regardless of the shape of these load lines, their average slope is increased by capacitive tuning of the load. The resulting reduction in change of B_0 with a given signal change reduces the effective control-winding inductance. Too much capacitance can result in a negative inductance in the control windings, producing an oscillatory condition.

In practice nearly the same improvement in response can be obtained by load tuning in the push-pull circuit as for the single core pair. The result is a practical, simple magnetic amplifier suitable for driving servomotors, especially in torque motor applications in which the motor speed is limited, preventing large changes in the motor impedance.

Frequency Response

The frequency response of an amplifier determines the effect it has on the stability of closed-loop servomechanisms. The only precaution necessary for predicting stability, even with nonlinear amplifiers, is that the signal phase shift and gain as functions of frequency must be obtained for the same amplifier conditions which exist in the servomechanism. It is therefore desirable to consider frequency-response capabilities of the noninductive magnetic amplifier.

The use of a signal-modulated carrier frequency does not necessarily imply a

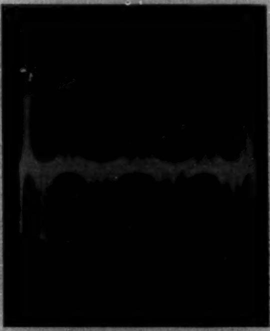

Fig. 12. Lissajous pattern with load current as ordinate and control voltage as abscissa. Supply frequency is 400 cps, signal frequency about 40 cps

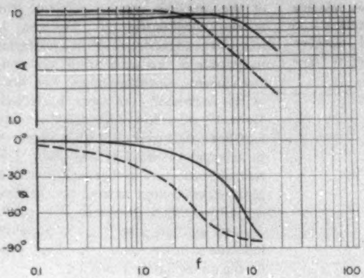

Fig. 13. Frequency response of single-polarity-output magnetic amplifier. Supply frequency is 400 cps. A is voltage gain, ϕ the phase angle, and f the frequency, cps. Dashed curves are for resistive load, solid curves for resistive-capacitive load

time delay or a phase lag as is often assumed. If the envelope of an amplitude-modulated signal at the output of an amplifier is in phase with the signal input, the amplifier does not contribute to system instability at that frequency. Some magnetic amplifiers, such as the Ramey circuit,[10,11] do provide a half-cycle delay resulting in a signal phase shift proportional to frequency. This delay is not inherent in all magnetic amplifiers, however.

It is necessary, of course, to avoid signal frequencies so high that the modulation is meaningless.

A magnetic amplifier with a truly noninductive control winding produces no phase lag. By keeping the signal amplitude small and carefully adjusting the load tuning capacitance for a given frequency so as to make the load line match a constant B_1 line for that quite limited operating point, zero phase shift can be produced at frequencies as high as one tenth of the supply frequency. Fig. 12 is a Lissajous pattern of output versus input signals showing the result of such adjustment of the magnetic amplifier described previously. The signal frequency is about 40 cps with a 400-cps power frequency. Without the tuning capacitance, approximately 90-degree lag results. A slight increase in capacitance makes the amplifier oscillatory.

For practical operation over reasonable signal ranges it is necessary to reduce the load tuning capacitance somewhat in order to avoid amplifier instability. The resultant slightly inductive magnetic amplifier does provide phase lag but is still a considerable improvement over the same amplifier with resistive load. Fig. 13 compares the frequency response of such an amplifier tuned to a practical degree and with a purely resistive load.

The frequency response of a pair of amplifiers connected in push-pull, driving a locked-rotor servomotor as the load, is shown in Fig. 14 for the cases of the load being tuned for unity power factor and (with increased capacitance) for improved frequency response. As with the single-ended magnetic amplifier, the load tuning has been limited to a value which retains good signal waveform. Higher frequency response is possible with degradation in waveform. It should be borne in mind that driving this amplifier from a high impedance source as would typically be done improves the response still further. The result is an amplifier suitable for use in servomechanisms requiring negligible phase lag at signal frequencies as high as 20 cps with 400 cps power.

Conclusions

There is no fundamental limitation to the speed of response possible from magnetic amplifiers. Response characteristics are determined by the change in average flux linkage with the control winding and the effective control resistance (including reflected resistances from other windings). Any relationships between response and voltage or power gain is not basic but is dependent, among other things, on the type of load used.

When no average flux change occurs during a transient, windings inductively coupled to the control winding are of no consequence. Even eddy currents and field propagation delays in the cores cannot cause delays when no change in flux is required.

One method of providing noninductive control is capacitive tuning of the loads of magnetic amplifiers in which the load current is inductively limited. Indeed, too much capacitance across the load can make a negative inductance of the control winding. The instability resulting from a negative inductance imposes the practical limitations of requiring a fixed load impedance and less than perfect tuning to allow for deviations between the shapes of the load line and the constant average flux density line, and for variations in supply voltage, supply frequency, bias, and load impedance. Even so, significant improvement can be had reliably by capacitive tuning.

The demonstration of instantaneous magnetic-amplifier response under special conditions is of academic interest, and the presently possible improvement in response of simple magnetic amplifiers is significant. Perhaps the introduction of the concept of noninductive magnetic amplifiers will open the way to truly fast-response magnetic amplifiers.

Appendix. Experimental Equipment

The saturable-reactor core pair used for all the experimental work described is shown schematically in Fig. 15. Each of the cores are 4-mil tape-wound hypersil toroids of 1.5-inch outside diameter, 1.0-inch inside diameter, and 0.375-inch height. A 1,000-turn load winding (N_L) is wound on each core. Then the 3,000-ohm 12,000-turn control winding (N_C) is wound on the pair of cores stacked together. The 500-turn feedback pickoff winding (N_F) is added for sensing changes in control flux linkages.

For all of the tests described terminals *2* and *4* were connected together making a series-connected magnetic amplifier, with terminals *1* and *3* as its load-winding terminals.

Fig. 16 is the schematic of the circuit suggested and used by John Cox, research engineer at Autonetics, for generating Fig. 2. When the switch is thrown to the I_{DC} position, the control current is controlled to the value determined by the setting of potentiometer *P* regardless of changes in a-c supply voltage. For each value of control current one of the constant I_{DC} lines is traced out as the alternating voltage is varied by turning the Variac *V*. When the switch is thrown to B_0, the control current is controlled in such a way as to maintain B_0 constant. Curves of constant B_0 can thus be traced by varying the alternating voltage for various values of B_0. By photographing the moving spot on the oscilloscope for several constant B_0 and several constant I_{DC} curves, Fig. 2 was obtained.

The load lines of Fig. 9 were obtained in a similar manner. A load of a 1,000-ohm resistor or this resistor paralleled by a 0.53-microfarad capacitor were added in series in the load circuit. With the Variac fixed at the proper position and the switch in the I_{DC} position, the load lines were traced out by varying the control current.

The transient-response oscillograms were taken using the circuit of Fig. 17 or modifications of it. The circuit as shown with different load resistors for Fig. 4 and with C_L being zero was used to obtain the instantaneous response of Figs. 4 through 6. By disconnecting the appropriate one of the relay switching circuits and adding capacitance to the load when needed, each of the other transients shown were obtained.

It should be noted the 3,000-ohm winding resistance in the control winding is the total effective control circuit resistance because of the very low output impedance of closed-loop operational amplifiers.

Frequency-response data were obtained by introducing a sinusoidal signal into the operational amplifier input and comparing the output of the magnetic amplifier with this input. Again, the only control circuit resistance is the 3,000-ohm winding resistance.

The push-pull circuit used for reversible output was made up from two of the saturable reactors shown in Fig. 15. Their load windings were connected as shown in Fig. 18. For the frequency-response tests, the control windings were driven in push-pull by two separate operational amplifiers, each connected the same as the one used for driving the single core pair.

Values of the variables associated with the transient- and frequency-response tests are given in Table I.

Discussion

R. M. Hubbard (Boeing Airplane Company, Seattle, Wash.): The authors have succeeded in presenting plausible explanations for two different phenomena which they attribute to the elimination of the control circuit inductance of a saturable-reactor type of magnetic amplifier. While one cannot dispute the fact that the experimental evidence does indeed indicate that fast response has been achieved, it is felt that the authors' historically acceptable analysis technique is not entirely convincing. Therefore an effort will be made to suggest an alternate means of explaining the observed phenomena.

In this discusser's opinion, the magnetic-amplifier art has reached a point in its development at which it is no longer necessary to use the analytical crutch of referring to the magnetic-amplifier control circuit as being characterized by a "sort of inductance." By denying the existence of such an inductance, one finds it relatively easy to explain its apparent elimination. Of course, the very existence of windings and, under some conditions, of an exponential-like response clearly suggests an inductive control circuit. Unfortunately, such an assumption puts one in the position of having to justify an inductance which, rather than having a magnitude dependent on the number of turns on a magnetic core, actually has its magnitude determined by the turns ratio, the value of the load resistance, and even the a-c supply frequency. Further, why does the control winding on a single-core amplifier exhibit no apparent inductance, while a combination of two single-core amplifiers is characterized by a highly inductive control circuit? How does one explain the fact that decreasing the L-R time constant by increasing the control circuit resistance yields radically different results between the case of the self-saturating circuit and that of the saturable-reactor circuit? In particular, the response of the former circuit approaches a pure delay while that of the later circuit approaches "instantaneous response," and neither circuit is characterized by exponential response. This discusser would like to suggest that the answers to these questions are beclouded by the practice of associating an equivalent linear inductance with magnetic-amplifier control circuits. Over restricted operating ranges, such an expediency yields usable results but when one is interested in the regions of fast response, the linear analogy crutch fails completely. It is further suggested that the answers to the subject questions can readily be found by simply recognizing the fact that the magnetic amplifier is a feedback system incorporating a time delay. This discusser has shown that such systems readily display exponential response, pure delay, or instantaneous response without the necessity for introducing the concept of inductance.[1,2] In fact, the use of delay lines with feedback is growing in both the radar field and the controls field, and the resultant "periodic filters" are in many cases characterized by exponential response.[3,4] Fortunately the absence of windings in many of the delay lines has prevented the users from falling into the trap of characterizing these devices by inductive input circuits. They have thus avoided the untenable position of having to explain a device whose input "inductance" is proportional to the length of the line in a manner analogous to the magnetic amplifier whose input "inductance" is proportional to the period of the a-c supply.

The authors are correct in their observation that if a change in output can be achieved with no appreciable change in the average flux linkages of either core then substantially instantaneous response will result. However, this discusser feels that the achievement of this condition has not been clarified by the authors' description of the theory. For example, can the technique for achieving instantaneous response by switching the load simultaneously with the input be achieved in the self-saturating class of circuit? The answer is obviously, "No, switching the load resistance can have no effect on transient response." Let us examine the reason for this basic difference. If the rectifiers are well behaved, any manipulation of the load circuit of a self-saturating circuit can only affect the gating core. Clearly the value of the average flux linkages of the gating core is predetermined and it is impossible to change the half-cycle average voltage across its load winding either by switching the load or by increasing the supply voltage. Thus E_{AC} cannot be increased with increasing load current and no modification of transient response is possible.

The important conclusion that should be drawn from the foregoing observations is that, in order to change E_{AC}, one must change the average flux linkages of the resetting core. This is true in both the self-saturating and in the saturable-reactor circuits and, in fact, any change in E_{AC} can be the result of only a change in the average load-winding voltage of a resetting core. Now the problem of achieving instantaneous response can be restated. How can one achieve a steady-state change in load current, and at the same time apply a compensating change to the average volts per turn of the windings on the resetting core so as to maintain constant the average volts per turn of that core? In essence one is asking that a change in output be accompanied by no change in input to the amplifier. No one could question the fact that such a condition would certainly result in no transient. It is obvious that the decoupling between load circuit and input (resetting core) afforded by the rectifiers in self-saturating circuits precludes the exercise of any control over the output quantity except by changing the input voltage. However, such is not the case with the saturable reactor. The absence of self-saturating rectifiers allows direct transformer coupling between load circuit and control circuit via the resetting core. This coupling path introduces 100% negative load current feedback. It is a simple matter, as the authors have seen, to switch out a portion of the load resistance and thereby cause an instantaneous change in load current. This new load current is transformer coupled directly into the control circuit where it produces a new IR drop across the control circuit resistance. For a steady state to exist the applied average control voltage must always equal this IR drop. Therefore, unless a cancelling change in control voltage is introduced an error voltage will be applied to the input (resetting core). If such a voltage is applied as input to the resetting core, our efforts to achieve a noninductive transient will not have been realized. Instead, a transient will ensue which will finally return the load current to its original value even though the load resistance has been changed. Once the original value of current is established, the resultant IR drop in the control circuit will again equal the constant applied control voltage and a steady state will exist. This so-called derivative effect, as described by the authors, is merely a demonstration of the fact that in a high-gain amplifier with 100% load current feedback, changes in load resistance can have only transitory effects upon the load current. It should be clear at this point that, if the load resistance and the control voltage are switched simultaneously, the change in control voltage can exactly compensate the change in control circuit IR drop caused by the load current. Thus no input would be applied to the resetting core. The net result is a change in output with no change in input, or a noninductive transient. One, of course, can question that the "brute force" technique of actually switching the output to achieve an instantaneous change in output can properly be termed "elimination of control circuit inductance." Also, it should be obvious that there is no danger of instability associated with the derivative effects discussed in the foregoing.

It is felt that the effect of a capacitive load on transient response involves a different phenomenon than is illustrated by the load-switching experiment. It is the discusser's

Vol.
Pt. I
195

opinion that the addition of capacitance to the load introduces a feedback phenomenon due to the resultant overlap or commutation effects. It has been shown by others that feedback can indeed produce fast, but not instantaneous, response as well as lead to stability problems in magnetic amplifiers. The fact that, unlike the previous case, the addition of capacitance to the load can produce equally good improvements in the transient response of both self-saturating and saturable-reactor classes of magnetic amplifiers suggests a somewhat different approach to the analysis problem.

It was previously stated that changes in the load circuit could not affect the resetting core in a self-saturating circuit and therefore could have no effect on transient response. However, the qualification that the rectifiers be well behaved is not actually satisfied in a capacitive circuit. The load voltage actually overlaps between the gating and the resetting half-cycles so that the load voltage does indeed effect the voltage applied to the resetting core. This constitutes negative feedback since an increasing load voltage applies an increasing voltage to the resetting core. The same sort of phenomenon occurs in the saturable-reactor circuit, and the net result is that transient response is speeded up by the negative feedback in the case of either circuit. The use of too much capacitance can result in the introduction of excessive negative feedback which produces an oscillatory condition. Thus, since control circuit inductance is nothing more than a manifestation of intrinsic feedback produced by the circuit connection, it is not surprising that the introduction of feedback can in fact "eliminate the inductance."

A New Control Amplifier Using a Saturable Current Transformer and a Switching Transistor

RAY E. MORGAN
MEMBER AIEE

THE PERFORMANCE of a large portion of electric equipment relies on dependable control amplifiers. Many control systems require fast-responding, compact, and economic amplifiers along with the demand for reliability. Saturable magnetic circuits combined with switching transistors promise good solutions for these control requirements.

This paper describes a magnetic-transistor amplifier that uses a saturable current transformer and a switching transistor; see Fig. 1. A 1-watt transformer and a transistor dissipating 2 watts proportionally control a 300-watt load. The saturable transformer transistor circuit is an oscillator, shown in Fig. 2, which is similar to the oscillator described in reference 1, except that a saturable current transformer is used in place of the saturable voltage transformer used in reference 1, and in Fig. 2 the load is placed in series with the transformer and transistor. The frequency of the oscillator of Fig. 2 is controlled by a direct current in a winding of the saturable transformer similar to the frequency controlled oscillator of reference 2, except in the circuit of Fig. 2, the load current I_L is controlled, as shown in the transfer characteristic of Fig. 3.

This paper describes methods of controlling the magnetic-transistor amplifier by a direct current and a variable resistor, and by a small integral magnetic amplifier that receives its power from the saturable current transformer transistor oscillator. The Delco *2N174* transistor is used, for the data in this paper and the saturable transformer core is made of 79% nickel, 17% iron, and 4% molybdenum.

Principle of Control

Basically, the magnetic-transistor amplifier operates as a chopper similar to the operation of the switch chopper of Fig. 4(A). The load current i_L waveshapes are shown in Fig. 4(B), (C) and (D), which are provided by opening and closing switch S_1, and these load current wave shapes are the same as those provided by the magnetic-transistor amplifier. The length of time that switch S_1 is closed remains approximately constant, while the length of time it is open is varied. The shorter the time it is open, the greater the load power becomes, while the longer the time it is open, the smaller the load power becomes. The load power of Fig. 4(A) is controlled by opening and closing switch S_1, which varies the time that the switch is open in relation to the time it is closed.

Operation of the Magnetic-Transistor Amplifier

The magnetic-transistor amplifier (Fig. 2) operates similarly to the switch chopper circuit of Fig. 4(A). The circuit of Fig. 2 oscillates and opens and closes the load circuit in the manner of switch S_1, Fig. 4(A), providing load current i_L waveshapes as shown in Fig. 4(B), (C) and (D).

Usually, the magnetic-transistor amplifier of Fig. 2 uses bias for the transistor, as shown in Fig. 5, with the use of resistors R_1 and R_2. The position of the transistor bias is shown in Fig. 6 (the steady-state characteristic of the transistor). The application of transistor bias

Paper 58-858, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 17, 1958; made available for printing April 18, 1958.

RAY E. MORGAN is with the General Electric Company, Schenectady, N. Y.

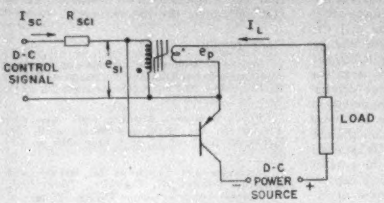

Fig. 2 (left). Circuit of magnetic transistor amplifier of Fig. 1, using saturable current transformer and switching transistor

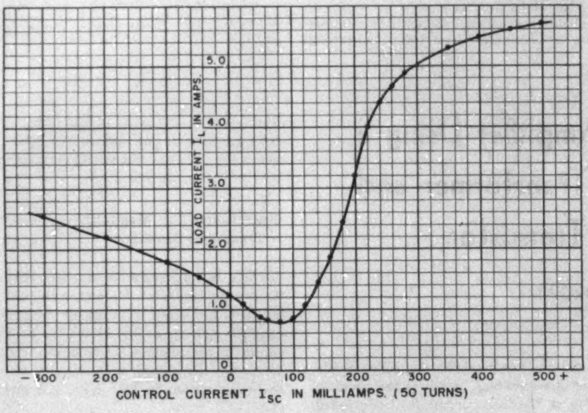
Fig. 3 (below). Transfer characteristic of circuit of Fig. 2



permits the circuit (Fig. 5) to maintain oscillation with a wider variation in the power source voltage (5% to 100% of the transistor's rated voltage) and ambient temperature, than that of the circuit of Fig. 2 without transistor bias. The transfer characteristic of Fig. 3 (obtained by the circuit of Fig. 5) is approximately the same for the circuit of Fig. 2.

Consider the operation of the circuit of Fig. 5 with control current $I_{SC}=+300$ ma (milliamperes); see Fig. 3. The circuit oscillates with the saturable current transformer core tracing the **B-H** hysteresis loop of *abcda* of Fig. 7. The secondary voltage e_{S1} is shown in Fig. 8(A). Starting with the transformer core at negative saturation (at point *d* of Fig. 7), the application of transistor bias supplied by resistors R_1 and R_2 (Fig. 5) permits a small amount of load current i_L to flow through the primary of the current transformer (forcing the transformer core flux density to point *a* of Fig. 7), producing secondary voltage e_{S1} see Fig. 5. Secondary voltage e_{S1} adds to the transistor bias voltage in a regenerative manner and forces the transistor to "snap full on." The transistor remains full on during the flux density excursion from *a* to *b* of Fig. 7. At point *b*, the saturable current transformer saturates. The secondary voltage (Fig. 5) now drops to $e_{S1}=0$, and the transistor turns almost off, decreasing the load current i_L in the primary winding. As current i_L decreases, voltage e_{S1} is induced negative (negative at the dot in Fig. 5) forcing the transistor to snap off ($i_L \cong 0$). With the transistor turned off, load current i_L and the transistor base current are negligible, leaving current I_{SC} to control the transformer core. Current I_{SC} forces the transistor to be held OFF by negative voltage e_{S1} (the flux density dropping from *c* to *d* of Fig. 7) until the saturable current transformer core reaches negative saturation at point *d*. After negative saturation, the secondary voltage drops to $e_{S1}=0$ and the transistor bias partially turns on the transistor sufficiently for the regenerative action of the current transformer to force the transistor to snap on and the oscillation continues. Distributed capacitance in the current transformer winding helps the circuit to snap on and snap off in the manner described in reference 1 in the saturable voltage transformer oscillator.

The reduction of control current to $I_{SC}=+200$ ma (Fig. 3) changes the **B-H** hysteresis loop to *abefa* in Fig. 7 and the secondary voltage e_{S1} waveshape is shown

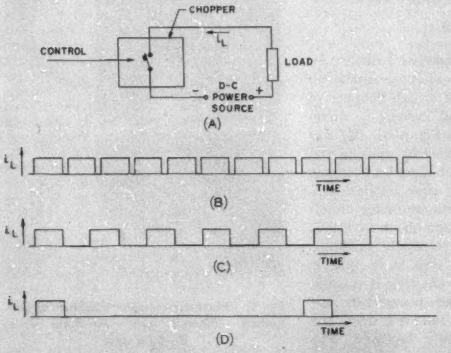


Fig. 4 (left). Switch chopper simulating operation of circuit of Fig. 2 and load current I_L waveshapes of Fig. 2. A—Switch simulator circuit. B—i_L at maximum output. C—i_L at one-half maximum output. D—i_L at minimum output

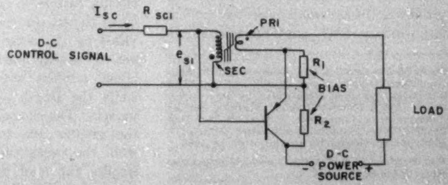
Fig. 5 (below). Same as Fig. 2 with transistor bias by resistors R_1 and R_2 added



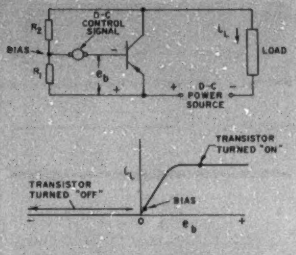


Fig. 6. Transistor circuit and steady-state characteristic of transistor, when not used as a switch, showing position of bias and position of characteristic of transistor when it is turned on and turned off

in Fig. 8(B). Likewise, reducing the control current to $I_{SC}=+100$ ma, the **B-H** loop is *abgha* (Fig. 7) and the waveshape of e_{S1} is shown in Fig. 8(C). In the same manner that high-frequency **B-H** hysteresis loops are wider (with a greater amplitude of H) than low-frequency loops, the greater the applied negative H (magnetomotive force in oersteds), the faster the flux density of the core traverses from positive to negative saturation. The time for the flux density excursion from c to d is less than the time for the flux density excursion from e to f and the time of the excursion from e to f is less than the excursion from g to h in Fig. 7. During the excursion of flux density from positive to negative saturation of the saturable current transformer (Fig. 5), control current I_{SC} is the main contributor of H to the core. With secondary voltage e_{S1} negative at the dot in Fig. 5 (forcing e_b of the transistor negative), the three terminals of the transistor are essentially open-circuit. For this condition, full control of the time the transistor is turned off is determined by current I_{SC}.

Decreasing control current to $I_{SC}<+100$ ma (Fig. 3) increases the frequency of the oscillator (Fig. 5) and gradually increases the load current I_L (Fig. 3). With $I_{SC}<+100$ ma, the saturable transformer traverses a minor **B-H** loop such as loop *nbmn* of Fig. 7. The flux density excursion of m to n being less than the excursion of g to h, the time the transistor is turned on and the time turned off is less for the **B-H** loop *nbmn* than **B-H** loop *habgh*, making the frequency increase as described in reference 2. As current I_{SC} is decreased below $I_{SC}=+100$ ma, the time off decreases more rapidly than the time on causing load current I_L to increase.

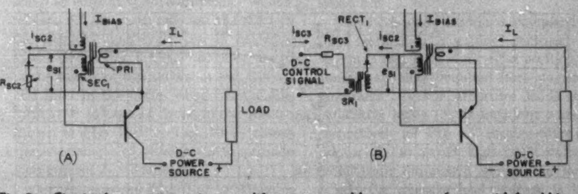

Fig. 9. Circuit of magnetic-transistor amplifier using saturable current transformer with fixed bias. A—Variable resistor control. B—Half-wave type of magnetic-amplifier control

The time the transistor is turned on remains constant as long as the saturable current transformer core maintains the full excursion from negative to positive saturation (minor **B-H** loops are avoided). During the time the transistor is turned on (a to b, Fig. 7), the saturable transformer operates as a regular current transformer. The power is supplied to the transformer by the primary current (i_L Fig. 5) and the secondary voltage is set by the secondary current and the secondary circuit resistance. The time the transistor is turned on is determined by $t_{ON}=N_{S1}\,\Delta\Phi/e_{S1}$, where N_{S1} is the number of turns on the secondary of the saturable transformer and $\Delta\Phi$ is the flux excursion of the transformer core. The turns N_{S1} and flux excursion $\Delta\Phi$ are design parameters of the saturable transformer. The secondary voltage e_{S1} is a function of design parameters of the saturable transformer, the secondary circuit components, the power source voltage, and load resistance.

For a given supply voltage, load, and

design, the time the transistor is turned on remains constant.

The average load current is controlled by the control current I_{SC} varying the time the transistor of the oscillator circuit (Fig. 5) is turned off.

Variable Resistor Control

The saturable current transformer transistor amplifier can be controlled by a variable resistor such as a rheostat, a thermistor, etc. The amplifier circuit for resistor control is shown in Fig. 9(A) (transistor bias is omitted for simplicity). Fig. 9(A) is the same as Fig. 2 except that control current I_{SC} is replaced by a fixed bias current I_{BIAS} (separate winding), rectifier $RECT_1$, and a variable resistor R_{SC3}. The bias current I_{BIAS}, Fig. 9(A) is set to provide load current of $I_L=5$ amperes (Fig. 3) with resistor $R_{SC3}=\infty$; see Fig. 9(A). With resistor $R_{SC3}=\infty$, the waveshape of secondary voltage e_{S1} is shown in Fig. 8(A), which shows the same waveshape provided by the circuit of Fig. 2. As resistor R_{SC3}, Fig. 9(A), is decreased, secondary current I_{SC3} increases (when e_{S1} is negative at the dot and flux density is dropping between c and d of Fig. 7). Current i_{SC3} provides ampere turns in winding SEC_1 that oppose the ampere turns provided by the bias winding. As current i_{SC3} increases, load current I_L decreases in similar manner to the circuit of Fig. 2 when control current is decreased from $I_{SC}=+300$ ma in Fig. 3. Load current I_L decreases as control resistor R_{SC3} Fig. 9(A), decreases until $R_{SC3}=0$, and then the forward resistance of rectifier $RECT_1$

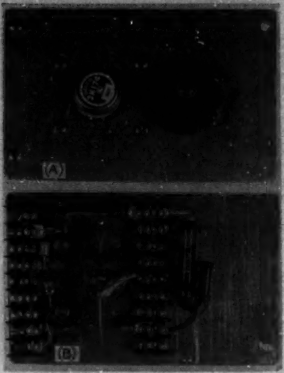

Fig. 14. Circuit of Fig. 11. A—Front view. B—Rear view

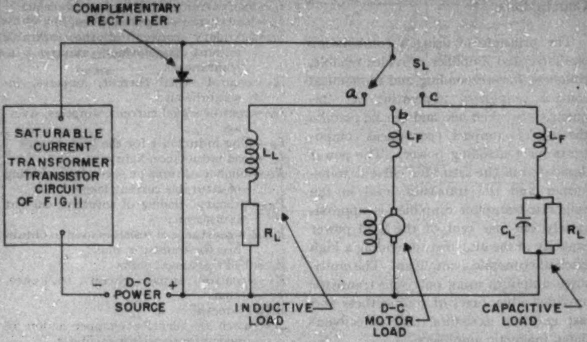

Fig. 15. Circuit of reactive loads for magnetic-transistor circuit of Fig. 11 using complementary rectifier with loads selected by switch S_L set at a, inductive; b, motor armature with inductance filter L_L, and c, capacitive load or capacitor-filtered load with inductive filter L_L

limits current i_{SC2} to set load current $I_L = 0.8$ amperes; see Fig. 3. With resistor $R_{SC2}=0$, the waveshape of secondary voltage e_{S1} is shown in Fig. 8(C).

Rectifier $RECT_1$ can be replaced by a fixed resistor, but rectifier $RECT_1$ prevents current from flowing in control resistor R_{SC2} during the interval of time the transistor is turned on (e_{S1} positive at the dot), thus reducing the power dissipated in resistor R_{SC2}.

Magnetic-Amplifier Control

The saturable current transformer transistor amplifier can be controlled by a small magnetic amplifier, Fig. 9(B) with the magnetic amplifier receiving its a-c power from the saturable current transformer transistor oscillator. Fig. 9(B) is the same circuit as that of Fig. 9(A) except that resistor R_{SC2} is replaced by saturable reactor SR_1. Reactor SR_1, combined with rectifier $RECT_1$, provides a half-wave self-saturating type of magnetic amplifier.[3,4] The magnetic amplifier controls the secondary current i_{SC2}, and controls the average load current I_L in a manner similar to that of the method resistor R_{SC2} of Fig. 9(A) in controlling the load current I_L, except that the magnetic amplifier phase controls current i_{SC2}.

The magnetic amplifier SR_1 of the Fig. 9(B) operates from the a-c voltage e_{S1} in a manner similar to that of a conventional self-saturating magnetic amplifier.[3,4] Different from a conventional magnetic amplifier, reactor SR_1 short-circuits its supply voltage e_{S1} when SR_1 saturates. When reactor SR_1 saturates, secondary voltage e_{S1} drops to about 5% of the voltage of e_{S1} when reactor SR_1 is unsaturated (typically, $e_{S1}=15$ volts with SR_1 unsaturated, and $e_{S1}=1.0$ volt with SR_1 saturated). The waveshapes of secondary voltage e_{S1} are shown in Fig. 10. When reactor SR_1 remains unsaturated for the entire cycle, load current $I_L=5$ amperes and voltage e_{S1} as shown in Fig. 10(A), which is the same as shown in Fig. 8(A). When reactor SR_1 remains saturated during the entire cycle of voltage e_{S1}, the waveshape of e_{S1} is shown in Fig. 10(C), which is similar to Fig. 8(C), and load current $I_L=0.8$ amperes. When reactor SR_1 is unsaturated at the start of the negative half-cycle (e_{S1} is negative at the dot in Fig. 9(B)), voltage e_{S1} starts at the same voltage shown in Fig. 10(A), and later in the cycle, when reactor SR_1 saturates, voltage e_{S1} drops to the voltage shown in Fig. 10(C). Fig. 10(B) shows the waveshape of voltage e_{S1} to provide load current $I_L=3$ amperes.

Control current I_{SC3}, Fig. 9(B), controls the time reactor SR_1 and saturates during the portion of the cycle that voltage e_{S1} is negative at the dot. The circuit of Fig. 9(B) is a combination of an oscillator and an amplifier that supplies high-frequency power (such as 1 kc to 10 kc) for a small magnetic amplifier, and provides a power amplifier stage. Fig. 11 shows the circuit of Fig. 9(B) except that a second stage is added to the magnetic amplifier. The magnetic amplifier of Fig. 11 is a 2-stage half-wave magnetic amplifier (commonly using a Supermalloy core for the first stage and an Orthonol or Deltamax core for the second stage) that controls the saturable current transformer transistor amplifier. The transfer characteristic of the circuit of Fig. 11 is shown in Fig. 12; the speed of response is shown in Fig. 13; and Fig. 14 shows the front and rear views of the circuit.

Reactive Loads

Reactive loads of both inductive and capacitive loads can be controlled by the magnetic-transistor amplifier. These reactive loads consist of control loads such as fields of motors or generators, solenoids, motor armatures, capacitive filtered loads, etc.

Inductive loads require a complementary rectifier (a "coasting" rectifier) as shown in Fig. 15 (switch S_L at position a) similar to that required for magnetic amplifiers. Motor armature loads and capacitive loads (S_L at positions b and c respectively of Fig. 15) require filter inductor L_F to avoid high peak voltage from being impressed across the load. When the average load voltage is low (minimum output power of the magnetic-transistor control), voltage peaks equal to the power source voltage, Fig. 4(D), occur across the load because of the very low resistance (sometimes 0.03Ω) of the transistor when it is turned on. Inductor L_F filters the load current, removing high peaks of voltage or current from being applied to the capacitive load. The complimentary rectifier (Fig. 15) is required to accompany inductor L_F due to the reaction of inductor L_F on the magnetic-transistor amplifier. Inductor L_F is normally small and economical oscillator frequency is commonly a kilocycle or greater.

Conclusions

The principle of using a combination oscillator and amplifier provides reliable, compact, fast-responding and economical control amplifiers. Operating at frequencies between one and ten kc permits the use of compact economical components for controlling power. The power dissipated in the saturable current transformer and the transistor used in the magnetic-transistor amplifier is approximately one per cent of the load power capacity of the amplifier, providing a high efficient economical amplifier. The multistage amplifier using only one transistor provides advantages of compactness and fast response exceeding that of conventional magnetic amplifiers.

Nomenclature

B = flux density in, kilogausses
C_L = load capacitor, microfarads (may be load filter or capacitive portion of load)
e_b = base-emitter voltage of transistor, volts, instantaneous
e_p = primary voltage of saturable current transformer, volts, instantaneous
e_S = secondary voltage of saturable current transformer, volts, instantaneous
H = magnetizing force of saturable current transformer core, oersteds
I_{BIAS} = bias current, amperes, average
i_L = load current, amperes, instantaneous
I_L = load current, amperes, average
i_S = secondary current of the saturable current transformer, amperes, instantaneous
i_{SC} = control signal current, amperes, instantaneous
I_{SC} = control signal current, amperes, average
L_F = filter inductance for the load, henrys
L_L = load inductance, henrys
N_S = number of turns on secondary winding of saturable current transformer
P_{RI} = primary winding of saturable current transformer
R_1, R_2 = resistance of resistors used to obtain bias for transistor, ohms
R_L = load resistance, ohms
R_{SC} = control signal circuit resistance, ohms
$RECT$ = rectifier
S_1 = switch to simulate chopper action of magnetic-transistor oscillator
S_L = load selector switch
SEC = secondary winding of saturable current transformer

Discussion

T. Bernstein (University of Wisconsin, Madison, Wis.): The use of switching transistors in conjunction with saturating cores is receiving a good deal of attention at present. The paper is certainly a valuable and interesting addition. One of the points that is open to further discussion is the relatively high minimum output which occurs. The ratio of maximum to minimum output is approximately ten to one. Is this more or less a fundamental limit or can greater ranges be obtained? Has the use of a more square loop core material been investigated for this circuit?

R. E. Morgan: Thank you Dr. Bernstein for your excellent comments and questions. The high minimum output of this magnetic-transistor amplifier is disturbing for some applications. The minimum output can be decreased by design, but a sacrifice is made in speed of response.

Core materials of Orthonol, Deltamax, Supermalloy, *4-79* mopermalloy, mumetal, and silicon iron have been investigated. For simplicity, only one core material (*4-79* mopermalloy) was used in this paper. The choice of core material depends upon the application. Frequently, "chopping" frequencies above 5,000 cycles per second are used and *4-79* mopermalloy is a good general-purpose material for these frequencies. At lower frequencies (less than 1,000 cycles per second) silicon iron is good. The square-loop materials such as Orthonol and Deltamax present problems of "snap action" with these bistable **B-H** loops.

A Comprehensive Study of Magnetic-Amplifier Design

I—A Practical Design Method

R. M. HUBBARD
ASSOCIATE MEMBER AIEE

M. M. BISHOP
NONMEMBER AIEE

IN THE past, magnetic-amplifier design papers have been conspicuously absent from the literature. It would appear that most practical design methods are primarily empirical in nature and tend to be dependent on a notebook of past successful designs. At the other extreme are a few theoretical design methods involving such things as analytical approximations of the nonlinearities of the core materials. It is the purpose of this paper to introduce a new, practical design method which is the outgrowth of a study of magnetic amplifier theory using block-diagram techniques[1] and which, by its nature, involves an absolute minimum of "cut and try."

The application of this design method permits both the design of a minimum size amplifier to meet a given set of design requirements and the determination of the capabilities of an amplifier when the requirements are not completely specified. This paper presents the basic essentials of the design method which are independent of such things as the type of core material used, the signal waveform, etc.

The introduction of these latter complicating factors represents a refinement on the general design method. This refinement is normally taken care of by modifying the original specified requirements of a given amplifier to take into account, for example, the limited linear operating range characteristic of the selected core material and the change in gain caused by different signal waveforms. By circumventing these second-order complicating factors, the design can be generalized such that only two, limiting, static operating points (saturation and cutoff) and the response time need be considered.

Nomenclature

A_i = Intrinsic amplification factor $[(\bar{R})(N_c/N_x)^2/R_c]$
A_N = Window area occupied by a given winding
A_{Nc} = Window area occupied by control winding

Paper 58-792, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 11, 1958; made available for printing April 8, 1958.

R. M. HUBBARD and M. M. BISHOP are with the Boeing Airplane Company, Seattle, Wash.

A_{Nx} = Window area occupied by load winding
A_w = Total usable window area of a core
a = Copper cross-sectional area of smallest usable wire
$\bar{B}$ = Average flux density
$\bar{B}_o$ = Average flux density at knee of a-c magnetization curve
D = Maximum allowable current density in wire
$\bar{E}$ = Average rectified voltage
$\bar{E}_c$ = Average rectified control (signal) voltage
E_d = Battery equivalent of diode threshold voltage
$\bar{E}_L$ = Average rectified load voltage
$(\bar{E}_L)_{co}$ = Average rectified load voltage at cut-off
$\bar{E}_{xo}$ = Average rectified voltage across N_x winding at knee of a-c magnetization curve
F = Fullness ratio of a given winding (ratio of A_N to A_w)
G_p = Amplifier power gain (ratio of $(\bar{V}\bar{A})_L$ to $(\bar{V}\bar{A})_{in}$)
$(G_p\eta_c)$ = Over-all power gain (ratio of $(\bar{V}\bar{A})_L$ to $(\bar{V}\bar{A})_c$)
$\bar{H}$ = Average magnetizing force
$\bar{H}_o$ = Average magnetizing force at knee of AC magnetization curve
HD = Minimum hole diameter in a fully wound toroidal core
$\bar{I}_c$ = Average rectified control current
$\bar{I}_L$ = Average rectified load current
$\bar{I}_R$ = Average rectified reset current
$\bar{I}_{xo}$ = Average rectified excitation current in N_x winding at knee of a-c magnetization curve
ID = Inside diameter of toroidal-core case
K = Internal voltage gain
K' = External voltage gain (ratio of $\Delta\bar{E}_L$ to $\Delta\bar{E}_c$)
k_R = Form factor of reset winding current
k_x = Form factor of load winding current
$\mathfrak{L}$ = Mean length magnetic path
M = Figure of merit $(G_p\eta_c/\tau_a - T)$
N = Number of turns in a given winding
N_c = Number of turns in a control winding
N_R = Number of turns in a reset winding
N_x = Number of turns in a load winding
OD = Outside diameter of toroidal-core case
Q_c = Ratio of reflected exciting impedance $\bar{R}(N_c/N_x)^2$ to control-circuit winding resistance (r_c)
Q_c^* = Ratio of reflected exciting impedance $\bar{R}(N_c/N_x)^2$ to resistance of the N_c winding (r_c^*)
Q_R^* = Minimum Q required for full control of the core by a reset winding operating at the rated current of the wire
Q_T^* = Maximum attainable Q corresponding to a winding which completely fills the usable window area A_w
Q_x = Ratio of exciting impedance $\bar{R}$ to load-circuit winding resistance r_x
Q_x^* = Ratio of exciting impedance $\bar{R}$ to resistance of the N_x winding r_x^*
$\bar{R}$ = Average exciting impedance of a core referred to the load (N_x) winding
$\bar{R}_N$ = Average exciting impedance referred to a given (N) winding
R_c = Total series resistance in the control circuit
r_c = Total series winding resistance in control circuit
r_c^* = Winding resistance of the control (N_c) winding
R_f = Forcing resistance in the control circuit
R_g = Signal generator internal resistance

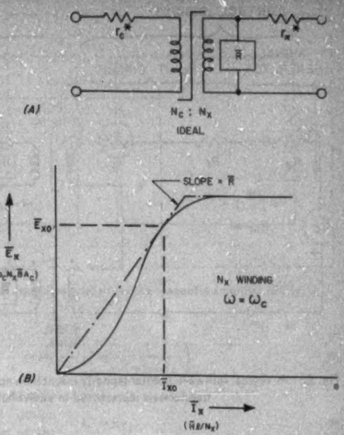

Fig. 1 (A). Saturable-transformer equivalent circuit (B). A-c magnetization curve for a typical saturable transformer

R_{IN} = Amplifier-input resistance as seen by the signal generator $(R_f + r_c)$
R_L = Effective load resistance (R_L' + diode dynamic resistance)
R_L' = True load resistance
R_s = Total signal-source resistance as seen by the amplifier $(R_g + R_f)$
r_w = Wire resistance per unit length
r_x = Total series winding resistance in load circuit
r_x^* = Winding resistance of the load (N_x) winding
S_1 = Length of shortest possible turn on a given core
S_2 = Length of longest possible turn on a given core
$\bar{S}_N$ = Mean length of turn of a given winding
$\bar{S}_T$ = Mean length of turn of a winding which completely fills usable window (A_w)
T = Time for one half-cycle of power supply frequency (ω_c)
$(\bar{V}\bar{A})_c$ = Average volt-amperes supplied by the signal generator
$(\bar{V}\bar{A}_{IN}$ = Average volt-amperes delivered to magnetic amplifier proper
$(\bar{V}\bar{A})_L$ = Average volt-amperes delivered to load
$(\bar{V}\bar{A})_x$ = Average core-excitation volt-amperes
α = Reset factor (Q_c^*/Q_R^*)
γ = Dynamic-range ratio $\Delta\bar{E}_L/(\bar{E}_L)_{co}$
η_c = Control circuit efficiency $(1/1 + R_s/r_c)$
η_L = Load circuit efficiency $(1/1 + r_x/R_L)$
ρ = Resistivity of wire
τ_a = Time for 63% response to a step change of control voltage
ω_c = Supply voltage angular frequency

The Saturable Transformer as the Basic Component of the Magnetic Amplifier

The basic element of which all magnetic amplifiers are built is the saturable transformer, which can be represented, see Fig. 1(A), in the equivalent circuit form previously introduced in the block-diagram analysis of magnetic amplifiers.[1] At the frequency of interest (ω_c), the nonlinear excitation impedance of the transformer is represented by an average resistance $(\bar{R})$ and the "ideal" transformer is taken as an ideal saturating-transformer. The resistance of the load (N_x) winding is r_x^* and that of the control (N_c) winding is r_c^*. Leakage reactance and winding capacitance are assumed negligible. The asterisks (*) are herein used to identify those parameters associated with the saturable transformer alone as against those parameters associated with the magnetic amplifier as a whole.

For purposes of this design method, the excitation impedance $(\bar{R})$ is assumed to have a single value which can be defined in terms of the normal a-c magnetization curve using the N_x winding. In Fig. 1(B) the average rectified voltage across the N_x winding, $\bar{E}_x$, is plotted versus the average rectified current that flows, $\bar{I}_x$. The only point of interest is that for "normal" excitation corresponding to the co-ordinates $(\bar{E}_{xo}, \bar{I}_{xo})$. Therefore, at the "knee" of the magnetization curve, the excitation impedance is

$$\bar{R} = \bar{E}_{xo}/\bar{I}_{xo} \tag{1}$$

and the core excitation in volt-amperes is

$$(\overline{VA})_x = (\bar{E}_{xo})(\bar{I}_{xo}) \tag{2}$$

The Q^* of a given winding is defined as the ratio of impedance to winding resistance, thus,

$$Q_x^* = \bar{R}/r_x^* \tag{3}$$

and

$$Q_c^* = \bar{R}(N_c/N_x)^2/r_c^* \tag{4}$$

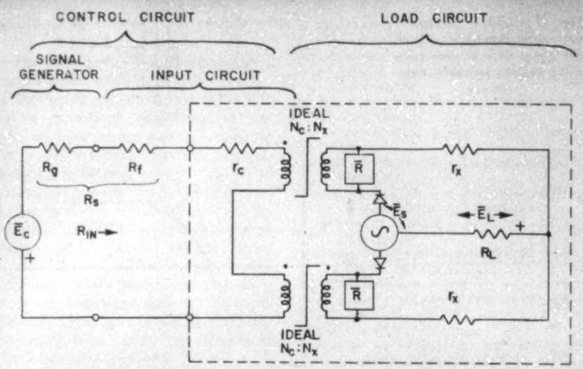

Fig. 2. A typical full-wave (center-tapped) magnetic amplifier with the component saturable transformers represented in equivalent circuit form

or

$$Q_c^* = \bar{R}'/r_c^* \tag{5}$$

The foregoing parameters associated with a particular transformer must be generalized for design purposes. Thus,

$$(\bar{R}_N/N^2) = (\bar{R}/N_x^2) = (\bar{R}'/N_c^2) = \omega_c\left[\frac{\bar{B}_o}{\bar{H}_o}\right]\left[\frac{A_c}{\mathcal{L}}\right] \tag{6}$$

In the foregoing, $\bar{B}_o$ and $\bar{H}_o$ are the average values of flux density and magnetizing force associated with operation under normally excited conditions (at $\omega = \omega_c$); whereas A_c is the net cross-sectional area of the core and $\mathcal{L}$ is the mean magnetic path length.

Using equation 6 and the following expression for the winding resistance of a given winding,

$$r_N = \frac{(\rho \bar{S}_N)}{(0.4A_N)}(N^2) \tag{7}$$

the Q_N^* of any winding is given by

$$Q_N^* = \frac{(0.4A_N)}{(\rho \bar{S}_N)}\left(\frac{1}{N}\right)^2\left\{(\omega_c)\left[\frac{\bar{B}_o}{\bar{H}_o}\right]\left[\frac{A_c}{\mathcal{L}}\right](N)^2\right\}$$

or

$$Q_N^* = \frac{(0.4A_N)}{(\rho \bar{S}_N)}(\omega_c)(\bar{B}_o/\bar{H}_o)(A_c/\mathcal{L}) \tag{8}$$

To simplify the succeeding work, sector winding on a toroidal core is assumed and, therefore, the mean length of turn ($\bar{S}_N$) of each winding is identical. The Q^* of a winding which completely fills the usable window area (A_w) is the maximum attainable and is designated Q_T^*. Thus,

$$Q_T^* = \frac{(0.4A_w)}{(\rho \bar{S}_T)}(\omega_c)\left[\frac{\bar{B}_o}{\bar{H}_o}\right]\left[\frac{A_c}{\mathcal{L}}\right] \tag{9}$$

The mean length of turn $\bar{S}_T$ for the fully wound core is characteristic of the dimensions of the particular core and has been formulated (see Appendix I) to permit the tabulation of Q_T^* for all standard toroidal cores.

A reset winding which is capable of fully resetting the core must have a Q^* which is equal to or greater than the minimum Q^* which corresponds to operation at the rated current of the wire in the reset winding. This minimum Q_R^* is given by (see Appendix I)

$$Q_R^* = (Q_T^*)\frac{(\bar{H}_o\mathcal{L})}{(0.4A_w)(D/k_R)} \tag{10}$$

In equation 10, k_R is the form-factor for the reset current, and D is the allowable current density in the wire. The ratio of the actual Q^* of a control winding, for example, to the minimum usable Q^* is designated the reset factor α. Thus,

$$\alpha = Q_c^*/Q_R^* \tag{11}$$

Since, for a given core, Q_N^* is proportional to the window area occupied by a given winding, then α is also the ratio of control-winding window area to minimum reset-winding window area. In addition, the ratio of α to the key parameter (Q_T^*/Q_R^*) is

$$\frac{\alpha}{Q_T^*/Q_R^*} = \frac{Q_c^*/Q_R^*}{Q_T^*/Q_R^*} = \frac{Q_c^*}{Q_T^*} \tag{12}$$

Clearly equation 12 is also the ratio of control-winding window area (A_{Nc}) to total usable window area (A_w). That is,

$$\frac{\alpha}{Q_T^*/Q_R^*} = \frac{A_{Nc}}{A_w} \tag{13}$$

The core excitation volt-amperes $(\overline{VA})_x$ may be generalized by noting that

$$(\overline{VA})_x = (\omega_c)(\bar{B}_o\bar{H}_o)(A_c\mathcal{L}) \tag{14}$$

and the per-turn voltage that a given winding can support under normally excited conditions is given by

$$\bar{E}/N = \omega\bar{B}_oA_c \tag{15}$$

The Design Parameters of a Typical Magnetic Amplifier

For purposes of illustrating this design method, the simple, full-wave, center-tapped magnetic amplifier of Fig. 2 has been selected as typical of the most common and most difficult to design class of magnetic amplifiers. The design problem resolves itself to the determination, from the magnetic amplifier, of the required values for the previously itemized saturable-transformer parameters and, from this, the selection of the optimum core.

In Fig. 2, the magnetic amplifier proper is defined as that circuitry enclosed by the dotted lines. Thus, the signal-generator resistance R_g and the forcing resistance R_f are external to the magnetic amplifier and their sum is considered to be the net signal source resistance R_s. The total winding resistance in the control circuit is designated r_c and the total winding resistance in the load circuit is r_x. Clearly the resistance of one saturable-transformer control winding r_c^* is one half of this total r_c, while the resistance of one saturable-transformer load winding r_x^* is equal to the total r_x. Note that as far as the signal

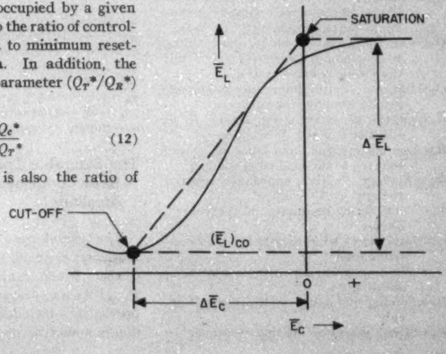

Fig. 3. A typical static transfer-characteristic for the circuit of Fig. 2

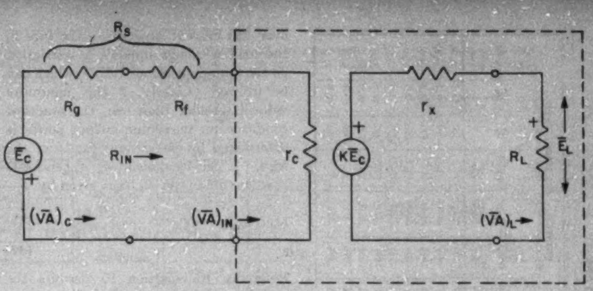

Fig. 4. Small-signal steady-state equivalent circuit for the magnetic amplifier of Fig. 2

generator is concerned, the input impedance of the magnetic amplifier (R_{in}) is the sum of the forcing resistance R_f and the winding resistance r_c.

A typical static transfer characteristic for the foregoing circuit is presented in Fig. 3. In line with the basic philosophy of this design technique, the requirements of a particular amplifier must be put in terms of the idealized transfer characteristic indicated by the dotted lines of Fig. 3. In other words, the requirements of the particular problem must be put into a form which is acceptable to the generalized design method. The transition from the typical, static transfer characteristic to the idealized one necessitates a familiarity with the characteristics of the core material to be utilized. Clearly, an extremely high order of accuracy is unobtainable in view of the relatively wide variation between the magnetic characteristics of different samples of the same core material. In fact, in the opinion of the authors, an attempt to design an amplifier such that the gain is solely determined by the characteristics of the core represents poor design techniques. That is, a certain amount of gain adjustment (e.g. negative feedback) is desirable to compensate for the normal variations in core characteristics.

Typically, the desired gain must be modified to account for the difference between the idealized transfer characteristic and the typical transfer characteristic at the same time that the ratio of gain to response time is held constant. In addition, the required dynamic range is modified to take into account the limited linear operating range which is characteristic of the particular core material.

In the following, the initial value of the control voltage is taken as zero such that $\Delta\bar{E}_c$ equals $\bar{E}_c$.

An important parameter associated with the static transfer characteristic is the dynamic-range ratio γ. This is defined by

$$\gamma=\Delta\bar{E}_L/(\bar{E}_L)_\infty \tag{16}$$

Of major importance in this design method is the small-signal steady-state equivalent circuit of Fig. 4. The key parameters, internal voltage gain K and 63% response time τ_a, are fixed by the circuit parameters according to the following expressions which were obtained from the previously mentioned block-diagram analysis.[1]

$$K=(A_i)(N_x/N_c) \tag{17}$$

$$\tau_a=(A_i+1)(\pi/\omega_c) \tag{18}$$

The intrinsic amplification factor A_i is defined as

$$A_i=\frac{\bar{R}(N_c/N_x)^2}{(R_s+r_c)} \tag{19}$$

Although the parameter A_i is valuable for purposes of analysis, this design method dictates the introduction of the parameter Q. If the Q of the control circuit is defined as

$$Q_c=\frac{\bar{R}'}{r_c}=\frac{\bar{R}(N_c/N_x)^2}{r_c} \tag{20}$$

and this is substituted into equation 19, the result is

$$A_i=(Q_c)\left(\frac{1}{1+R_s/r_c}\right) \tag{21}$$

If further, the efficiency of the control circuit η_c is defined as the ratio of the power delivered into the magnetic amplifier proper $(\overline{VA})_{in}$ to the total power drawn from the signal generator $(\overline{VA})_c$, it can be seen that

$$\eta_c=\frac{1}{1+R_s/r_c} \tag{22}$$

Thus, the intrinsic amplification factor is

$$A_i=Q_c\eta_c \tag{23}$$

the internal voltage gain is

$$K=(Q_c\eta_c)(N_x/N_c) \tag{24}$$

and the response time is

$$\tau_a=[(Q_c\eta_c)+1]\{\pi/\omega_c\} \tag{25}$$

The external voltage gain K' can be seen to be

$$K'=\frac{\Delta\bar{E}_L}{\Delta\bar{E}_c}=(K)\left(\frac{R_L}{R_L+r_x}\right)$$

or

$$K'=(K)\left(\frac{1}{1+r_x/R_L}\right) \tag{26}$$

If the efficiency of the load circuit η_L is defined as the ratio of load power to total power delivered by the amplifier, then

$$\eta_L=\left(\frac{1}{1+r_x/R_L}\right) \tag{27}$$

and

$$K'=K\eta_L \tag{28}$$

The various powers (average volt-amperes) can be determined by inspection to be as follows:

Load Power:

$$(\overline{VA})_L=\frac{(\Delta\bar{E}_L)^2}{R_L} \tag{29}$$

Signal Power:

$$(\overline{VA})_c=\frac{(\Delta\bar{E}_c)^2}{R_s+r_c} \tag{30}$$

Input Power:

$$(\overline{VA})_{in}=\frac{(\Delta\bar{E}_c\eta_c)^2}{r_c} \tag{31}$$

The foregoing may be normalized (see Appendix I) with respect to the core excitation volt-amperes to yield:

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=Q_x\left[\frac{(R_L/r_x)}{(1+R_L/r_x)^2}\right] \tag{32}$$

$$\frac{(\overline{VA})_c}{(\overline{VA})_x}=\frac{1}{(Q_c\eta_c)} \tag{33}$$

$$\frac{(\overline{VA})_{in}}{(\overline{VA})_x}=\frac{1}{Q_c} \tag{34}$$

It can readily be shown (see Appendix I) that the dynamic range ratio γ is given by

$$\gamma=Q_x/(1+R_L/r_x) \tag{35}$$

By inspection, the maximum voltage the transformer load winding (N_x) must support (at cutoff) is given by

$$\bar{E}_{x0}=\bar{E}_L/\eta_L \tag{36}$$

For maximum output power from a given amplifier at a given frequency, the load resistance (R_L) should be matched to the internal impedance (r_x). How-

ever, the current capacity of the wire in the load windings imposes a restriction on the minimum value of R_L/r_x which can be utilized. Clearly, if this minimum value is greater than one, the practical condition for maximum output power is determined by the current rating of the wire. It can be shown (see Appendix I) that the minimum R_L/r_x is given by

$$\text{Min}\,(R_L/r_x)=(Q_T^*)\frac{(\bar{H}_0\mathcal{L})}{(0.4A_w)(D/k_x)(2)}-1 \qquad (37)$$

Reference to equation 10 permits the simplification

$$\text{Min}'(R_L/r_x)=\left(\frac{Q_R^*}{2}\,\frac{k_x}{k_R}\right)-1$$

or, if k_R is assumed equal to k_x,

$$\text{Min}\,(R_L/r_x)=\frac{Q_R^*}{2}-1,\; k_R=k_x \qquad (38)$$

It is also informative to express such parameters as power gain, figure of merit, gain-bandwidth product, etc. in terms of Q. Therefore, the amplifier power gain is

$$G_p=\frac{\overline{(VA)}_L}{\overline{(VA)}_{in}}=Q_xQ_c\left[\frac{R_L/r_x}{(1+R_L/r_x)^2}\right] \qquad (39)$$

and the over-all power gain is

$$G_p\eta_c=\frac{\overline{(VA)}_L}{\overline{(VA)}_c}=Q_x(Q_c\eta_c)\left[\frac{R_L/r_x}{(1+R_L/r_x)^2}\right]$$

It is of particular interest to note that if the gain-bandwidth product and the figure of merit are defined as follows, simple expressions result.

$$\text{Gain bandwidth:}\quad K/(\tau_a-T)=(N_x/N_c)\left(\frac{1}{T}\right),\; T=\pi/\omega_c \qquad (40)$$

$$\text{Figure of merit:}\quad M=\frac{G_p\eta_c}{\tau_a-T}=\left[\frac{\overline{(VA)}_L}{\overline{(VA)}_x}\left(\frac{1}{T}\right)\right] \qquad (41)$$

At this point, the bulk of the necessary magnetic-amplifier design equations for a simple amplifier with no bias winding have been itemized. It will be seen that equations 11, 16, 25, 29, 30, 32, 33, and 35 contain sufficient information to permit the selection of the optimum core for a simple amplifier. In addition, equations 24, 26, 27, and 36 will be shown to be necessary for the selection of the number of turns on each winding.

Prior to the selection of the core for a particular amplifier, the foregoing information must be put in terms of saturable-transformer parameters rather than magnetic-amplifier parameters. This simply involves, for the subject circuit, the substitution

$$Q_c^*=2Q_c \qquad (42)$$

and

$$Q_x^*=Q_x \qquad (43)$$

Tabulation of Core Parameters

The heart of this design method is the tabulation of the important parameters for all of the standard core sizes and magnetic materials which are considered to be suitable for magnetic amplifier application. For simplicity, the tabulation lists the values of the various parameters at a reference frequency, 1,000 cycles per second. Appropriate correction factors permit the determination of the values at any other frequencies of interest.

Table I is an abstract of a more complete tabulation of the important core parameters and is based on a new proposal for standardizing core sizes, which is treated in the second part of this paper. All of the tabulated parameters have been previously treated herein with the exception of Max $\overline{(VA)}_L$. This parameter is the limiting value of output power which results when the available window is completely filled with load windings (i.e., $\alpha\rightarrow 0$) and the wire is operated at its rated current (i.e., $R_L/r_x=\text{Min}\,R_L/r_x$).

Thus,

$$\text{Max}\,\overline{(VA)}_L=\overline{(VA)}_x(Q_T^*)\times\left[\frac{\text{Min}\,(R_L/r_x)}{(1+\text{Min}\,(R_L/r_x))^2}\right] \qquad (44)$$

It should be pointed out that, although Table I is based on a new list of proposed standard cores, such a tabulation could be obtained for any toroidal cores. In fact, this design technique is applicable to any core (e.g. *D-U* laminations, *C* cores, etc.) which lend themselves to the calculations of the afore-mentioned design parameters.

The Mechanics of the Design Method

The actual mechanics of this design method can best be introduced by the use of the flow diagram of Fig. 5 and the corresponding block diagram of the necessary expressions, Fig. 6. The following steps in the design procedure can be visually traced by the use of these diagrams.

I. Given: Statement of the Problem

(A) Load circuit

1. The maximum swing in load voltage (ΔE_L) corresponding to operation from saturation to cutoff determines the required dynamic range.
2. The allowable load voltage at cutoff

Fig. 5. Flow diagram for magnetic amplifier design

$(\bar{E}_L)_{\infty}$ affects the over-all efficiency but is normally determined by the nature of the desired static transfer characteristic.

3. The effective load resistance R_L includes the real load (R_L'), the dynamic forward resistance of the rectifier (see Appendix I), and the internal impedance of the carrier supply.

4. The ratio of effective load resistance to load-winding resistance (R_L/r_x) determines the regulation and the efficiency (η_L) of the load circuit.

(B) Control circuit

1. The full swing of control voltage $\Delta\bar{E}_c$ drives the amplifier from saturation to cutoff. (The addition of bias is a relatively simple matter which is herein omitted for the sake of brevity.)

2. R_g is the internal resistance of the signal generator.

3. The effective amplifier-input resistance (R_{in}) is the sum of the real steady-state input resistance r_c and the forcing resistance R_f. The input resistance should be stated as a minimum allowable value, since the required value of R_f may produce a higher R_{in} than specified.

4. The 63-per-cent response time (τ_a) has a minimum value which is limited by the time (T) for one-half cycle of the supply (carrier) frequency (ω_c).

5. The available carrier frequency is ω_c.

II. Amplifier Parameters Required for Core Selection

(A) The maximum signal power delivered to the effective load resistance is $(\overline{VA})_L$. The power dissipated at cutoff is normally wasted power.

(B) The required dynamic range ratio (γ) fixes a minimum allowable value on Q_x for a given design.

(C) The maximum control current $\bar{I}_c$ (or $\Delta\bar{I}_c$) is determined by the allowable input resistance (R_{in}), the signal-generator internal resistance (R_g) and the maximum control $\bar{E}_c$ (or $\Delta\bar{E}_c$). The total power supplied by the signal generator is merely the product of control voltage ($\bar{E}_c$) and control current ($\bar{I}_c$).

(D) The required response time (τ_a) and the carrier frequency (ω_c) fix the value of the important parameter $Q_c\eta_c$ (from equation 25).

III. The Core Parameters Required for Core Selection

The core parameters are simply determined from the preceding amplifier parameters.

(A) As previously mentioned:

$Q_x{}^* = Q_x$, $Q_c{}^* = 2Q_c$, $r_x{}^* = r_x$ and $r_c{}^* = r_c/2$.

(B) The product $Q_x{}^*(\overline{VA})_x$ is a constant which is fixed by the previously specified design requirements, namely, $(\overline{VA})_L$ and R_L/r_x (from equation 32).

(C) The minimum value of $Q_x{}^*$ was previously determined by the required γ.

(D) The maximum allowable value of the core excitation power $(\overline{VA})_x$ is determined by the available signal power $(\overline{VA})_c$ and the required response time (τ_a) (from equation 33).

(E) A reset winding which is capable of fully controlling the core must have a Q^* which is equal to or greater than the tabulated $Q_R{}^*$ corresponding to current limited operation of the winding. If $\bar{I}_c$ is equal to or greater than the rated current of the smallest wire which can be wound, then $Q_c{}^*$ is equal to $Q_R{}^*$ (i.e. $\alpha = 1$). However, if $\bar{I}_c$ is less than the rated current of the smallest wire which can be wound, then $Q_c{}^*$ must be greater than $Q_R{}^*$. In the latter case, the ratio of $Q_c{}^*$ to $Q_R{}^*$ (or α) is merely the ratio of the rated current of the smallest wire which can be used (i.e. aD/k_R) to the available control current ($\bar{I}_c$).

IV. Core Selection

(A) If the tabulated minimum $R_L/r_x{}^*$ is not equal to or less than the required $R_L/r_x{}^*$ which was specified in the original statement of the problem, then the tabulated value must be used and the resultant change in $Q_x{}^*(\overline{VA})_x$ calculated in section III(B).

(B) The tabulated value of $(\overline{VA})_x$ for the

Fig. 6. Block diagram incorporating necessary design equations for use in Fig. 5

selected core must be equal to or less than the maximum value determined in section III(D).

(C) Since $Q_x{}^*(\overline{VA})_x$ must be constant, $Q_x{}^*$ for a given core can be determined by dividing this constant by $(\overline{VA})_x$ for the given core. Clearly the resultant $Q_x{}^*$ must be less than the tabulated $Q_T{}^*$ by the amount $Q_c{}^*$ (where $Q_c{}^* = \alpha Q_R{}^*$). Good design dictates the selection of the smallest core which will meet the requirements outlined in both (B) and (C).

V. Selected-Core Parameters

(A) The core is capable of supporting $(\bar{E}/N)$-volts per turn under conditions of normal excitation.

(B) The usable window area (A_w) is that fractional part of the total window area which may be utilized in view of limitations of the winding machine.

(C) The area (A_N) occupied by a given winding can be determined by noting that winding area is a linear function of winding Q^*. Thus:

1. $A_{NX} = (Q_x{}^*/Q_T{}^*)A_w$
2. $A_{NC} = (Q_c{}^*/Q_T{}^*)A_w$

(D) The excitation impedance per turn squared $(\bar{R}_N/N^2)$ is a constant for the particular core.

(E) Utilization of the parameters S_1 and S_2 permits the calculation of the mean length of turn $(\bar{S}_N)$ of the windings.

1. The length of the shortest possible turn on the core (S_1) corresponds to the turn which is wound directly on the case.
2. The length of the longest possible turn on the core (S_2) corresponds to the turn which completely fills the usable window area A_w.

VI. Amplifier Parameters Not Required for Core Selection

(A) The load circuit efficiency (η_L) is fixed by the required R_L/r_x or by Min (R_L/r_x) of the selected core depending on which is larger.

(B) The maximum voltage $(\bar{E}_{xo})$ which must be supported by the load (N_x) winding corresponds to the maximum swing in load voltage. Thus, $\bar{E}_{xo} = \Delta\bar{E}_L/\eta_L$.

(C) The internal voltage gain K is merely the external voltage gain K' (i.e. $\Delta\bar{E}_L/\Delta\bar{E}_c$) divided by the load circuit efficiency η_L.

(D) The required-turns ratio (N_x/N_c) is fixed by the desired voltage gain K and by $Q_c\eta_c$ (via the desired τ_a).

(E) The supply voltage $\bar{E}_s$ is the sum of the following:

1. The maximum load voltage (at saturation), $\Delta\bar{E}_L + (\bar{E}_L)_{co}$, divided by the load circuit efficiency η_L.
2. The battery equivalent of the forward threshold voltage of the rectifier $\bar{E}_d$ (see Appendix I).

VII. Determination of Number of Turns

(A) Load winding

The number of turns (N_x) on the load winding is simply

$N_x = (\bar{E}_{xo})/(\bar{E}/N)$

(B) Control winding

The number of turns (N_c) on the control winding can be determined from the turns ratio (N_x/N_c) and N_x.

VIII. Determination of Wire Size and Winding Resistance

(A) Load winding

Using the number of load turns (N_x) and the allotted window area A_{NX}, the usable wire size may be determined from Fig. 7. The larger wire size of two choices should be used and any resultant change in A_{NX} noted for future use.

(B) Control winding

1. If α is greater than one, the control winding (N_c) should be wound with the previously determined smallest usable wire size. N_c turns of this size wire should fill the allotted window area (A_{NC}).
2. If α is equal to one, the number of control turns N_c and the allotted window area A_{NC} should be used to determine the wire size from Fig. 7. Any resultant change in A_{NC} should be noted for future use.

(C) Winding resistance

The determination of the resistance of each winding involves first the calculation of the mean length of turn S_N and then the calcu-

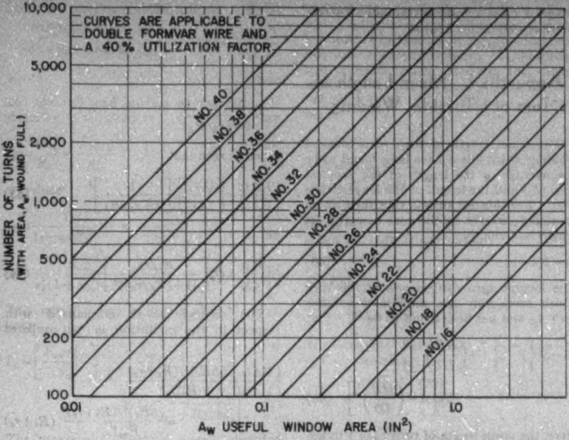

Fig. 7. Number of turns in a given winding versus usable window area assuming a space factor of 0.4

lation of the winding resistance (r_N) from the number of turns and the wire resistance per unit length (r_w) (from Table II).

1. Using the area of each winding which corresponds to the selected wire size, the fullness ratio ($F_N = A_N/A_w$) is calculated. Thus,

$F_x = A_{NX}/A_w$, $F_c = A_{NC}/A_w$

2. For sector winding, the mean length of turn of each winding is

$\bar{S}_N = S_1 + (F_x + F_c) \quad (S_2 - S_1)/2 = \bar{S}_x = \bar{S}_c$

3. The resistance of each winding ($r_N{}^*$) can be determined by substituting in the expression

$r_N{}^* = (N)(\bar{S}_N)(r_w)$

Thus:

$r_x{}^* = (N_x)(\bar{S}_x)(r_w)$, $r_c{}^* = (N_c)(\bar{S}_c)(r_w)$

Note that

$r_x = r_x{}^*$, $r_c = 2r_c{}^*$

IX. Final Calculations Using Actual Parameters of Selected Core

The actual values of several of the amplifier parameters can be compared with the design values by utilizing the foregoing information which applies to the selected core.

(A) The required forcing resistance can be calculated; or the experimental determination of this resistance is a simple matter, since at this point one is assured that the selected value will result in an amplifier which meets the initial design requirements.

The determination of R_f involves the calculation of the required value of control circuit efficiency (η_c) based on the actual Q_c and the value of ($Q_c\eta_c$), which was dictated by the required response time. Therefore, the actual value of Q_c (which will normally differ somewhat from the value determined in section III) must be calculated for the selected core. Thus,

$Q_c = (\bar{R}_N/N^2)(N_c{}^2)/r_c$

and $\eta_c = (Q_c\eta_c)/Q_c$

The value of the forcing resistance R_f can then be determined by using the definition of η_c (equation 22).

(B) The actual values of the load circuit efficiency (η_L) and the load circuit Q, (Q_x) can be determined by using the actual value of r_x which was determined in section VIII(C).

(C) The actual voltage gain (K'), the steady-state power gain (G_p) and the figure of merit M can also be determined by using the parameters associated with the selected core.

Sample Design Problem

A sample design problem which will serve to further illustrate the use of this technique is presented in Appendix II. Clearly, in the interest of simplicity, only the essential parts of the design method have been presented. Thus, such considerations as the type of core material to be used, the selection of rectifiers, the linearity and drift requirements, etc., have not been mentioned.

THE "OPEN-ENDED" DESIGN

Often, a design problem is of such a nature that insufficient information is specified in the statement of the problem. For example, everything might be known except the available signal power so that the requirement would be to design an amplifier which would give a specified performance with a minimum input power. Or it might be necessary to determine the maximum output power attainable with a given input power. Certainly there are any number of combinations of such open-ended designs. This design technique, in slightly modified form, lends itself to the optimization of such designs. For example, it has been seen that

$$\frac{(\overline{VA})_L}{(\overline{VA})_x} = Q_x\left[\frac{R_L/r_x}{(1+R_L/r_x)^2}\right] \tag{32}$$

* At 2 milliamperes per circular mil.

$$M=\left[\frac{(\overline{VA})_L}{(\overline{VA})_x}\right]\left[\frac{1}{T}\right] \tag{41}$$

and

$$G_p=Q_xQ_c\left[\frac{R_L/r_x}{(1+R_L/r_x)^2}\right] \tag{39}$$

If the core window area is to be fully utilized it can be seen that

$$Q_x{}^*=Q_T{}^*-Q_c{}^*=Q_x$$

and

$$Q_c{}^*=2Q_c.$$

Therefore

$$(\overline{VA})_L\propto(Q_T{}^*-Q_c{}^*),$$
$$M\propto(Q_T{}^*-Q_c{}^*)$$

and

$$G_p\propto(Q_c{}^*/2)(Q_T{}^*-Q_c{}^*)$$

Clearly, to maximize $(\overline{VA})_L$ and M, the window area should be completely filled by the load winding (i.e. $Q_c{}^*\rightarrow 0$).

However, to maximize G_p it can be seen that

$$\frac{\partial G_p}{\partial Q_c{}^*}=0=Q_T{}^*-2Q_c{}^*$$

$$\therefore Q_c{}^*=Q_T{}^*/2$$

Thus, the window should be half filled by the control winding to maximize the power gain G_p. The application of the other design equations permits similar general conclusions to be drawn as an aid to the solution of this particular type of design problem.

The list of proposed standard cores, of which Table I is a partial abstract, is particularly valuable when the design requirements are incompletely specified. This fact is clarified by Part II of this paper which describes the performance parameters which are inherent to the tabulation.

In effect, the core tabulation contains information as to the relative performance of the tabulated cores rather than merely the physical dimensions.

Conclusions

The basic principles of a new magnetic-amplifier design technique based on a study of magnetic amplifier theory have been presented. This technique involves an absolute minimum of purely empirical data but, at the same time, avoids impractical analytical studies of the nonlinearities inherent to the component magnetic elements. Although a typical full-wave magnetic amplifier circuit has been taken as a model for this presentation, the design technique can readily be extended to half-wave magnetic amplifiers, toroidal transformers, and a variety of other magnetic circuits.

Appendix I. Mean Length of Turn of a Toroidal Winding

The mean length of turn of a toroidal winding which fills A_w has been found to be the average of the length of the shortest turn (S_1) and the length of the longest turn (S_2). The shortest turn is that turn which is wound directly on the core case and its length is obviously,

$$S_1=2(h+b) \tag{45}$$

The longest turn corresponds to the turn which completely fills the usable window area A_w and has been found to be

$$S_2=S_1\left\{1-2\left[1-\left(\frac{HD}{ID}\right)^2\right]\right\}+2\bar{S}_0\left[1-\left(\frac{HD}{ID}\right)^2\right] \tag{46}$$

Here, the mean length of turn $\bar{S}_0$ of a hypothetical winding which completely fills the window area (no hole) is given by

$$\bar{S}_0=2h\left[1+\frac{(0.98)(ID/OD+0.306)}{(1-ID/OD)(h/b)}\right], \quad ID/OD\leq 0.9 \tag{47}$$

Formulation of Minimum Q^* of a Reset Winding

The reset current required for full control is given by

$$\bar{I}_R=\bar{H}_o\mathcal{L}/N_R \tag{48}$$

and the maximum allowable current in the winding is

$$\begin{aligned}\text{Max } \bar{I}_R&=(D/k_R)(a_{\text{wire}})\\&=(D/k_R)(0.4A_{NR}/N_R)\end{aligned} \tag{49}$$

Therefore, under current limited conditions,

$$\bar{H}_o\mathcal{L}/N_R=(D/k_R)(0.4A_{NR}/N_R) \tag{50}$$

and

$$A_{NR}=\frac{\bar{H}_o\mathcal{L}}{(D/k_R)(0.4)} \tag{51}$$

But, since

$$\frac{Q_N{}^*}{A_N}=\frac{Q_T{}^*}{A_w}=\frac{Q_R{}^*}{A_{NR}}$$

it can be seen that

$$Q_R{}^*=Q_T{}^*\left[\frac{\bar{H}_o\mathcal{L}}{(D/k_R)(0.4A_w)}\right] \tag{52}$$

Core Excitation Volt-Amperes as a Normalizing Factor

The output power normalized with respect to the excitation volt-amperes is as follows

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=\frac{(\Delta\bar{E}_L)^2/R_L}{\bar{E}_{xo}\bar{I}_{xo}}=\frac{(\bar{E}_{xo})^2(\eta_L)^2/R_L}{\bar{E}_{xo}\bar{I}_{xo}}=\frac{(\bar{E}_{xo}/\bar{I}_{xo})(\eta_L)^2}{R_L}$$

Since

$$\frac{\bar{E}_{xo}/\bar{I}_{xo}}{r_x}=Q_x$$

and

$$\eta_L=\frac{1}{1+(r_x/R_L)}$$

it can be seen that

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=\left[\frac{Q_xr_x}{R_L}\right]\left[\frac{1}{1+r_x/R_L}\right]^2 \tag{53}$$

or

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=Q_x\left[\frac{R_L/r_x}{[1+(R_L/r_x)]^2}\right] \tag{54}$$

The control power normalized with respect to the excitation in volt-amperes is

$$\frac{(\overline{VA})_c}{(\overline{VA})_x}=\frac{(\Delta E_c)^2/(R_s+r_c)}{\bar{E}_{xo}\bar{I}_{xo}}=\frac{(\Delta E_c)^2/(R_s+r_c)^2}{\bar{E}_{xo}\bar{I}_{xo}}\,(R_s+r_c)$$

But,

$$\frac{\Delta E_c}{R_s+r_c}=\frac{\bar{H}_o\mathcal{L}}{N_c}=(N_x/N_c)(\bar{I}_{xo})$$

and

$$\eta_c=\frac{1}{1+R_s/r_c}$$

Therefore,

$$\frac{(\overline{VA})_c}{(\overline{VA})_x}=\frac{[(N_x/N_c)(\bar{I}_{xo})]^2(r_c)}{(\bar{E}_{xo}\bar{I}_{xo})(\eta_c)} \tag{55}$$

or

$$\frac{(\overline{VA})_c}{(\overline{VA})_x}=\frac{1}{Q_c\eta_c} \tag{56}$$

The input power normalized with respect to the excitation in volt-amperes is

$$\frac{(\overline{VA})_{IN}}{(\overline{VA})_x}=\frac{[(\bar{I}_{xo})(N_x/N_c)]^2r_c}{\bar{E}_{xo}\bar{I}_{xo}} \tag{57}$$

or

$$\frac{(\overline{VA})_{IN}}{(\overline{VA})_x}=\frac{1}{Q_c} \tag{58}$$

Formulation of the Dynamic Range Ratio

Since

$$\gamma=\frac{\Delta\bar{E}_L}{(\bar{E})_{L\infty}}=\frac{\bar{E}_{xo}/\eta_L}{\bar{I}_{xo}R_L}$$

$$Q_x=(\bar{E}_{xo}/\bar{I}_{xo})/r_x$$

and

$$\eta_L=\frac{1}{1+r_x/R_L}$$

it can be seen that

$$\gamma=Q_x/(1+R_L/r_x) \tag{59}$$

FORMULATION OF THE MINIMUM VALUE OF R_L/r_x

For a practical design

$$\gamma >> 1$$

and the full load current at saturation is given by

$$I_L = \frac{\Delta\bar{E}_L}{R_L} = \frac{E_{x0}\eta_L}{R_L}$$

or; since

$$\eta_L = \frac{1}{1+r_x/R_L}$$

$$I_L = \frac{E_{x0}}{r_x(1+R_L/r_x)} \tag{60}$$

This may be put in terms of Q_x^* as follows:

$$I_L = \left[\frac{E_{x0}/I_{x0}}{r_x}\right]\left[\frac{I_{x0}}{1+R_L/r_x}\right] = Q_x^*\left[\frac{(\bar{H}_o\mathcal{L})/N_x}{1+R_L/r_x}\right] \tag{61}$$

The maximum allowable current dictated by the current capacity of the wire is as follows

$$\text{Max } I_L = 2(D/k_x)(a_{\text{wire}}) = 2(D/k_x)(0.4A_{Nx}/N_x) \tag{62}$$

Therefore,

$$Q_x\left[\frac{\bar{H}_o\mathcal{L}/N_x}{1+\text{Min}(R_L/r_x)}\right] = 2(D/k_x)(0.4A_{Nx}/N_x) \tag{63}$$

and

$$1+\text{Min }(R_L/r_x) = Q_x\left[\frac{\bar{H}_o\mathcal{L}}{(D/k_x)(0.4A_{Nx})^*}\right] \tag{64}$$

Since

$$\frac{Q_x}{A_{Nx}} = \frac{Q_x^*}{A_{Nx}} = \frac{Q_T^*}{A_w}$$

it can be seen that

$$\text{Min }(R_L/r_x) = Q_T^*\left[\frac{\bar{H}_o\mathcal{L}}{(D/k_x)(0.4A_w)(2)}\right] - 1 \tag{65}$$

RECTIFIER EQUIVALENT CIRCUIT

It has been found valuable to simplify the nonlinear characteristics of magnetic-amplifier rectifiers by assuming the equivalent circuit to be an equivalent battery (of approximately 0.5 to 0.7 volt) with an internal impedance corresponding to the dynamic forward resistance of the rectifier. This simplification is particularly valid in the case of silicon fused-junction diodes.

Appendix II. Sample Design Problem

The actual (practical) design requirements must be put into a form which is acceptable to this design method in terms of the idealized static transfer-characteristics. The utilization of such a modification of the practical design requirements is typified by the sample design problem which follows. Clearly, the sample problem cannot include all of the practical considerations which are based on knowledge and common sense, therefore, this design method is merely intended to serve as a valuable guide rather than as a "cook book."

I. Given

$\Delta\bar{E}_L = 23$ volts
$(\bar{E}_L)_{\infty} = 0.1$ volt
$R_L = 115$ ohms

$R_L/r_x = 30$
$\omega_c = 6{,}280$ radians per second
$\bar{E}_c = 2$ volts

$R_g = 250\ \Omega$
$R_{IN} = 250\ \Omega$ (min)
$\tau_a = 0.002$ second

II. Amplifier Parameters Required for Core Selection

$$(\overline{VA})_L = \frac{(\Delta\bar{E}_L)^2}{R_L} = \frac{(23)^2}{(115)} = 4.60 \text{ volt-amperes}$$

$$\gamma = \frac{\Delta\bar{E}_L}{(\bar{E}_L)_{\infty}} = \frac{(23)}{(0.1)} = 230$$

$$\text{Min } Q_x = \gamma(1+R_L/r_x) = (230)(1+30) = 7{,}130$$

$$I_c = \frac{\bar{E}_c}{R_g+R_{IN}} = \frac{(2)}{(250+250)}\ 0.004 \text{ ampere}$$

$$(\overline{VA})_c = \bar{E}_cI_c = (2)(0.004) = 0.008 \text{ volt-ampere}$$

$$Q_c\eta_c = \left[\frac{\tau_a}{\pi/\omega_c} - 1\right] = \left[\frac{0.002}{\pi/6280} - 1\right] = 3$$

III. Core Parameters Required for Core Selection

$$Q_x(\overline{VA})_x = \frac{(\overline{VA})_L}{\left[\dfrac{R_L/r_x}{(1+R_L/r_x)^2}\right]} = \frac{4.60}{\left[\dfrac{30}{(31)^2}\right]} = 147.5$$

$$\text{Max } (\overline{VA})_x = (\overline{VA})_c(Q_c\eta_c) = (0.008)(3) = 0.024 \text{ volt-ampere}$$

If *#40* is the smallest wire which can be wound,

$$\alpha = (a)(D)/(k_R)(I_c) = (7.76\times10^{-6})(2{,}546)/(1.11)(0.004) = 4.45$$

IV. Core Selection

A study of the core tabulation, Table I, reveals that *HYMU-80* core *#16* most closely fits the foregoing requirements. Thus:

The required $R_L/r_x(30)$ is greater than the tabulated minimum $R_L/r_x(12.7)$, and the maximum allowable $(\overline{VA})_x(0.024)$ is greater than the actual $(\overline{VA})_x(0.0173)$.

$$\text{Required } Q_x^* = \frac{Q_x(\overline{VA})_x}{\text{TAB}(\overline{VA})_x} = \frac{147.5}{0.0173} = 8{,}518$$

Since the minimum $Q_x^*(7{,}130)$ dictated by the required value of γ is less than the foregoing $Q_x^*(8{,}518)$, γ is not a limiting factor.

$$Q_c^* = \alpha Q_R^* = (4.45)(27.3) = 121$$

Since the required Q_T^* is the sum of Q_x^* and Q_c^*, $Q_T^* = (8{,}518)+(121) = 8{,}639$, and this value is less than the tabulated $Q_T^*(9{,}900)$.

In order to determine the required wire sizes, the area occupied by each winding must be determined as follows:

$$A_{Nx} = \frac{Q_x^*}{Q_T^*}A_w = \frac{(8{,}518)}{(9{,}900)}(0.123) = 0.106 \text{ sq. in.}$$

$$A_{Nc} = \frac{Q_c^*}{Q_T^*}A_w = \frac{(121)}{(9{,}900)}(0.123) = 0.0015 \text{ sq.in.}$$

VI. Amplifier Parameters Required for Core Selection

$$\eta_L = \frac{1}{\left(1+\dfrac{r_x}{R_L}\right)} = \frac{1}{\left(1+\dfrac{1}{30}\right)} = 0.968$$

$$\bar{E}_{x0} = \Delta\bar{E}_L/\eta_L = (23/0.968) = 23.76 \text{ volts}$$

$$K = \frac{\Delta\bar{E}_L/\eta_L}{\bar{E}_c} = \frac{(23/0.968)}{(2)} = 11.88 \text{ volts per volt}$$

$$(N_x/N_c) = \frac{K}{(Q_c\eta_c)} = \frac{(11.88)}{(3)} = 3.96 \text{ turns per turn}$$

$$\bar{E}_s = \frac{\Delta\bar{E}_L+(\bar{E}_L)_{\infty}}{\eta_L} + \bar{E}_d = \frac{(23+0.1)}{(0.968)} + (0.7) = 24.6 \text{ volts}$$

VII. Determination of Number of Turns

$$N_x = \bar{E}_{x0}/\left(\frac{E}{N}\right) = \frac{(23.76)}{(0.055)} = 432 \text{ turns}$$

$$N_c = N_x/\left(\frac{N_x}{N_c}\right) = \frac{(432)}{(3.96)} = 109 \text{ turns}$$

VIII. Wire Size and Resistance of Windings

Using the turns per area curves (Fig. 7) and areas from section IV,

$N_x = 432$ turns, if *#29* wire, $A_{Nx} = 0.11$ sq. in.

$N_c = 109$ turns, if *#40* wire, $A_{Nc} = 0.0022$ sq. in.

The difference between actual areas and those found under section IV is due to the finite number of wire sizes available.

$$F_x = \frac{A_{Nx}}{A_w} = \frac{0.11}{0.123} = 0.895$$

$$F_c = \frac{A_{Nc}}{A_w} = \frac{0.0022}{0.123} = 0.0179$$

$$\bar{S}_n = S_1 + (F_x+F_c)\left(\frac{S_2-S_1}{2}\right) = (1.112) + (0.913)\left(\frac{1.510-1.112}{2}\right) = 1.294 \text{ inches}$$

$$r_x^* = N_x\bar{S}r_w = (432)(1.294)\left(\frac{0.0818}{12}\right) = 3.79\ \Omega,\ (r_x = r_x^*)$$

$$r_c^* = N_c\bar{S}r_w = (109)(1.294)\left(\frac{1.049}{12}\right) = 12.3\ \Omega,\ (r_c = 2r_c^* = 24.6\ \Omega)$$

IX. Final Amplifier Calculations

Because of the practical limitations on wire sizes, the actual parameters become

$$Q_c=(\bar{R}_N/N^2)\frac{N_c^2}{r_c}=(0.179)(109)^2/(24.6)$$
$$=86.5$$

$$\eta_c=\frac{(Q_c\eta_c)}{Q_c}=\frac{(3)}{(86.5)}=0.0347$$

$$R_F=r_c\left(\frac{1}{\eta_c}-1\right)-R_g=$$
$$(24.6)\left(\frac{1}{0.0347}-1\right)-250=434\text{ ohms}$$

$$Q_z=(R_N/N^2)(N_z^2/r_z)$$
$$=(0.179)(432)^2/(3.79)=8{,}814$$

$$\eta_L=\frac{1}{(1+r_z/R_L)}=\frac{1}{\left(1+\frac{3.79}{115}\right)}$$
$$=0.968,\ \frac{R_L}{r_z}=\frac{115}{3.79}=30.34$$

$$G_p=Q_zQ_c\left[\frac{R_L/r_z}{(1+R_L/r_z)^2}\right]$$
$$=(8{,}814)(86.5)\left[\frac{30.34}{(31.34)^2}\right]=29{,}650$$

$$M=\frac{G_p\eta_c}{r_a}=\frac{(29{,}650)(0.0347)}{(0.002)}=516{,}500$$

It is interesting to note that the value of R_F which was previously determined yields a higher input resistance than the required value. Thus, although the amplifier performance meets the specifications, the actual required signal power is less than that specified.

A Comprehensive Study of Magnetic-Amplifier Design

II—Toroidal-Core Dimensional Ratios as Factor in Magnetic-Amplifier Design

R. M. HUBBARD
ASSOCIATE MEMBER AIEE

M. M. BISHOP
NONMEMBER AIEE

THE APPLICATION of a block-diagram method of analysis for magnetic amplifiers[1] to practical design problems has produced a design technique which involves a minimum of cut and try while yielding near-optimum results. An indispensable part of this design method is a tabulation of the physical constants of the available toroidal magnetic cores. In the process of tabulating standard cores, it became clear to the authors that there was absolutely nothing systematic about the manner in which standard core sizes had evolved in the past. Clearly, with one exception,[2] little attempt had been made to determine the optimum dimensional ratios or to eliminate overlaps and gaps in the power ratings of the cores. It would appear that magnetic amplifiers were destined to suffer the same fate as vacuum-tube amplifiers as a result of this random development of core sizes. Therefore, an investigation to determine the effect of toroidal-core dimensional ratios on magnetic-amplifier performance was undertaken. Subsequent to the initiation of this investigation the first proposal for standardizing toroidal-core sizes was published by the AIEE Committee on Magnetic Amplifiers.[3]

This paper is intended to present a logical method by which the optimum toroidal-core configurations can be determined and also to propose a list of standard core sizes which effectively covers the practical range of power levels with a minimum number of cores. The proposed AIEE Standards on recommended tape widths and limiting values of dimensional ratios are adhered to wherever possible.

Nomenclature

A_c = net cross-sectional area of core
A_N = window area occupied by a given winding
A_{Nc} = window area occupied by control winding
A_{Nz} = window area occupied by load winding
A_w = total usable window area of core (herein, total window area)
$\bar{B}$ = average flux density
$\bar{B}_0$ = average flux density at knee of a-c magnetization curve
b = core build-up
D = maximum allowable current density in wire
$\bar{E}$ = average rectified voltage
$\bar{E}_c$ = average rectified control (signal) voltage
$\bar{E}_d$ = battery equivalent of diode threshold voltage
$\bar{E}_L$ = average rectified load voltage
$\bar{E}_{z0}$ = average rectified voltage across N_z winding at knee of a-c magnetization curve
G_p = amplifier power gain (ratio of $(\bar{V}\bar{A})_L$ to $(\bar{V}\bar{A})_{IN}$)
$(G_p\eta_c)$ = over-all power gain (ratio of $(\bar{V}\bar{A})_L$ to $(\bar{V}\bar{A})_c$)
$\bar{H}$ = average magnetizing force
$\bar{H}_0$ = average magnetizing force at knee of a-c magnetization curve
h = core height
h/b = ratio of core height to build-up
$\bar{I}_c$ = average rectified control current
$\bar{I}_L$ = average rectified load current
ID/OD = ratio of core inside diameter (ID) to outside diameter (OD)
k_R = form factor of reset current
k_z = form factor of load current
l = mean length of magnetic path
M = figure of merit $(G_p\eta_c)/(\tau_a-T)$
N = number of turns in a given winding
N_c = number of turns in control winding
N_z = number of turns in load winding
Q_b = ratio of reflected exciting impedance $\bar{R}(N_b/N_z)^2$ to bias circuit winding resistance r_b
$Q_b{}^*$ = ratio of reflected exciting impedance $\bar{R}(N_b/N_z)^2$ to resistance of the N_b winding $r_b{}^*$
Q_c = ratio of reflected exciting impedance $\bar{R}(N_c/N_z)^2$ to control circuit winding resistance r_c
$Q_c{}^*$ = ratio of reflected exciting impedance $\bar{R}(N_c/N_z)^2$ to resistance of the N_c winding $r_c{}^*$
$Q_n{}^*$ = the Q of a given winding
$Q_r{}^*$ = minimum Q required for full control of core by reset winding operating at rated current of the wire
$Q_T{}^*$ = the Q of winding which completely fills the usable window area (A_w)
Q_z = ratio of exciting impedance $\bar{R}$ to load circuit winding resistance r_z
$Q_z{}^*$ = ratio of exciting impedance $\bar{R}$ to resistance of the N_z winding $r_z{}^*$
$\bar{R}$ = average exciting impedance of core referred to the load (N_z) winding
R_c = total series resistance in control circuit
r_c = total series winding resistance in control circuit
$r_c{}^*$ = winding resistance of the control (N_c) winding
R_f = forcing resistance in control circuit
R_g = signal generator internal resistance
$r_n{}^*$ = winding resistance of a given winding
R_s = total signal source resistance as seen by the amplifier (R_g+R_f)
r_w = wire resistance per-unit length
r_z = total series winding resistance in load circuit

Paper 58-793, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 11, 1958; made available for printing April 8, 1958.

R. M. HUBBARD and M. M. BISHOP are with the Boeing Airplane Company, Seattle, Wash.

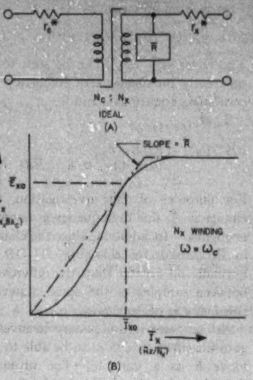

Fig. 1 (left). Saturable-transformer equivalent circuit (A). A-c magnetization curve for typical saturable transformer (B)

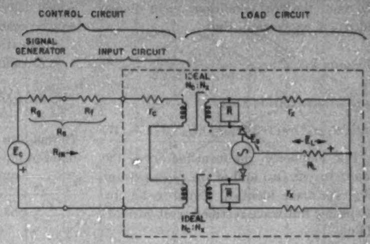

Fig. 2 (right). A typical full-wave (center-tapped) magnetic amplifier with component saturable transformers represented in equivalent-circuit form

r_x^* = winding resistance of the load (N_x) winding
S = length of one turn of a given winding
S_1 = length of shortest possible turn on a given core
S_2 = length of longest possible turn on a given core
$\bar{S}_n$ = mean length of turn of a given winding
$\bar{S}_0$ = mean length of turn of a winding which completely fills the core window
T = time for one half-cycle of power supply frequency (ω_c)
$(\overline{VA})_c$ = average volt-amperes supplied by signal generator
$(\overline{VA})_{IN}$ = average volt-amperes delivered to magnetic amplifier proper
$(\overline{VA})_L$ = average volt-amperes delivered to load
$(\overline{VA})_x$ = average core excitation volt-amperes
V_c = iron volume of magnetic core
V_T = total volume of wound core
V_w = winding volume of wound core
α = reset factor (Q_c^*/Q_R^*)
γ = dynamic range ratio $\Delta \bar{E}_L/(\bar{E}_L)_{co}$
η_c = control circuit efficiency $1/(1+R_S/r_c)$
η_L = load circuit efficiency $1/(1+r_x/R_L)$
ρ = resistivity of wire in given winding
τ_a = time for 63% response to step change in control voltage
ω_c = supply voltage angular frequency

Saturable Transformer

The saturable transformer has been introduced in Part I of this paper as the basic element of which all magnetic amplifiers are constructed. It has been found reasonable to represent the nonlinear excitation impedance of a transformer (utilizing the high-remanence cores typical of magnetic amplifiers) as an average resistance ($\bar{R}$). Thus, the equivalent circuit of such a transformer can be represented as in Fig. 1(A). Herein the star (*) is used to designate those parameters associated with the component saturable transformers as against those parameters associated with the magnetic amplifier as a whole. The a-c magnetization curve of Fig. 1(B) serves to illustrate the characteristics of a typical saturable transformer.

In Part I of this paper, the magnetic-design equations and performance parameters were expressed in terms of those parameters which are characteristic of the saturable transformer. Herein, it is intended to go one step further and relate the design equations to the physical and magnetic constants of the magnetic cores. In order to generalize this investigation the toroidal core is considered to be a solid uncased core which can be wound completely full.

The excitation impedance is given by

$$\bar{R} = (N_x^2)(\omega_c)[(\bar{B}_0/\bar{H}_0)(A_c/l)] \tag{1}$$

or more generally

$$\bar{R}_N/N^2 = (\omega_c)[(\bar{B}_0/\bar{H}_0)(A_c/l)] \tag{2}$$

The resistance of any winding (assuming a space factor of 0.4) is

$$r_N^* = (\rho)(N)(\bar{S}_N)\left(\frac{N}{0.4A_n}\right) \text{ or}$$

$$r_N^* = (\rho)(\bar{S}_N)\left(\frac{N^2}{0.4A_n}\right) \tag{3}$$

For simplicity, sector winding is assumed such that the mean length of turn of each winding ($\bar{S}_N$) is the same. The Q^* of a winding is defined as the ratio of its impedance to its winding resistance, thus

$$Q_N^* = \frac{(\omega_c)(B_0/H_0)(A_c/l)(0.4A_N)}{(\rho)(\bar{S}_N)} \tag{4}$$

or

$$Q_N^* = (K_1)(A_c/l)(A_N/\bar{S}_N) \tag{5}$$

where

$$K_1 = \left[\frac{(0.4)(\omega_c)}{(\rho)}\right](\bar{B}_0/\bar{H}_0) \tag{6}$$

The Q^* of a winding which completely fills the core window area A_w is

$$Q_T^* = (K_1)(A_c/l)(A_w/\bar{S}_0) \tag{7}$$

The minimum Q^* which a reset winding can have and still be capable of full control of the core corresponds to current-limited operation of the winding. Thus it has been shown (see Part I) that

$$Q_R^* = \frac{(\bar{H}_0 l)(Q_T^*)}{(0.4A_w)(D/k_R)} \tag{8}$$

or

$$Q_R^* = K_2(A_c/\bar{S}_0) \tag{9}$$

where

$$K_2 = \frac{(\omega_c)(\bar{B}_0)}{(\rho)(D/k_R)} \tag{10}$$

This minimum Q^* is a valuable normalizing factor. Therefore, the normalized control winding Q^* is

$$Q_c^*/Q_R^* = \alpha \tag{11}$$

and, since Q^* is proportional to winding area,

$$Q_T^* = Q_x^* + Q_c^* \tag{12}$$

Therefore,

$$(Q_T^*/Q_R^*) - \alpha = Q_x^*/Q_R^* \tag{13}$$

INTRODUCTION OF MAGNETIC-AMPLIFIER DESIGN EQUATIONS

In Part I of this paper it was shown that the output power $[(\overline{VA})_L]$ of a full-wave magnetic amplifier (see Fig. 2) normalized with respect to the core excitation power $[(\overline{VA})_x]$ is given by

$$\frac{(\overline{VA})_L}{(\overline{VA})_x} = Q_x\left[\frac{R_L/r_x}{(1+R_L/r_x)^2}\right] \tag{14}$$

and further that

$$\frac{(\overline{VA})_L}{(\overline{VA})_x} = Q_x^*\left[\frac{R_L/r_x^*}{(1+R_L/r_x^*)^2}\right] \tag{15}$$

The condition for maximum output power corresponds to current-limited operation of the load winding (N_x) and this may or may not be a matched condition, i.e., $R_L/r_x = 1$. The current capacity of the load winding limits the degree with which one can approach a matched condition in the same fashion that the current capacity of a reset winding limits the minimum usable Q.

In fact, the two conditions yield almost identical expression, thus

$$1+\min(R_L/r_x{}^*)=\frac{(\bar{H}_0 l)(Q_T{}^*)}{(0.4A_w)(D/k_x)(2)} \tag{16}$$

and from equation 8

$$\min(R_L/r_x{}^*)=(1/2)(k_x/k_R)(Q_R{}^*)-1 \tag{17}$$

For simplicity, the form factors of the load current (k_x) and of the reset current (k_R) are made identical (equal to 1.1) by assuming full-wave rectified reset current. Thus,

$$\min(R_L/r_x{}^*)=\frac{Q_R{}^*}{2}-1,\ k_x=k_R=1.1 \tag{18}$$

If the load winding (N_x) is operated at its rated current, then

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=Q_x{}^*\left\{\frac{\min(R_L/r_x{}^*)}{[1+\min(R_L/r_x)]^2}\right\} \tag{19}$$

or

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=Q_x{}^*\left[\frac{(Q_R{}^*-2)}{(Q_R{}^*)^2}\right](2) \tag{20}$$

Substitution of equation 13 into equation 20 yields

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=\left(\frac{Q_T{}^*}{Q_R{}^*}-\alpha\right)\left(1-\frac{2}{Q_R{}^*}\right)(2) \tag{21}$$

In order to simplify this investigation by removing frequency as a variable, it is necessary to assume that

$$Q_R{}^*\gg 2 \tag{22}$$

The fact that this is a reasonable assumption in the frequency range above approximately 1,000 radians per second can be verified by substituting typical values into equation 9. The general conclusions which are reached with the aid of this assumption fortunately are not invalidated in the low-frequency range in which Q_R is not much greater than one. It is interesting to note at this point that the most important single factor which determines whether or not the load can be matched is the supply frequency.

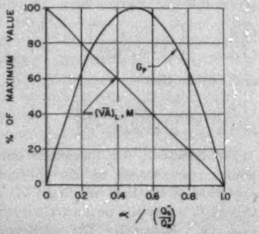

Fig. 3. Load power $[(\overline{VA})]_L/\omega_c$, figure of merit ($M/\omega_c$), and steady-state power gain (G_p/ω_c), normalized with respect to their maximum values, versus the normalized reset factor (α)

Application of expression 22 to equation 21 yields

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=\left(\frac{Q_T{}^*}{Q_R{}^*}-\alpha\right)(2),\ Q_R{}^*\gg 2 \tag{23}$$

It was also seen in Part I that the normalized input power is given by

$$\frac{(\overline{VA})_{IN}}{(\overline{VA})_x}=\frac{1}{Q_c}=\frac{2}{Q_c{}^*} \tag{24}$$

or

$$\frac{(\overline{VA})_{IN}}{(\overline{VA})_x}=\frac{2}{\alpha Q_R{}^*} \tag{25}$$

Therefore the steady-state power gain (G_p) can be determined from equations 23 and 25 as follows

$$G_p=\frac{(\overline{VA})_L}{(\overline{VA})_{IN}}=(\alpha Q_R{}^*)[(Q_T{}^*/Q_R{}^*)-\alpha] \tag{26}$$

Also, one definition of figure of merit M has been shown to be

$$M=\frac{G_p\eta_c}{\tau_a-T}=\left[\frac{(\overline{VA})_L}{(\overline{VA})_x}\right]\left(\frac{\omega_c}{\pi}\right) \tag{27}$$

Thus,

$$M=2[(Q_T{}^*/Q_R{}^*)-\alpha]\left(\frac{\omega_c}{\pi}\right) \tag{28}$$

It is interesting to note that the foregoing expression is substantially in agreement with the early work of Carleton and Horton.[4]

To remove supply frequency (ω_c) as a variable, the foregoing may be reduced as follows

$$\frac{(\overline{VA})_L}{(\overline{VA})_x}=\left[\frac{(\overline{VA})_L}{(\omega_c)(\bar{B}_0\bar{H}_0)(A_c l)}\right] =[(Q_T{}^*/Q_R{}^*)-\alpha](2) \tag{29}$$

or

$$(\overline{VA})_L/\omega_c=2[(\bar{B}_0\bar{H}_0)(V_c)][(Q_T{}^*/Q_R{}^*)-\alpha] \tag{30}$$

In addition,

$$G_p/\omega_c=(\alpha Q_R{}^*/\omega_c)(Q_T{}^*/Q_R{}^*-\alpha) \tag{31}$$

and from equation 9

$$Q_R{}^*/\omega_c=(K_2/\omega_c)(A_c/\bar{S}_0) \tag{32}$$

The application of equation 10 to the foregoing yields

$$Q_R{}^*/\omega_c=\left[\frac{(\bar{B}_0)}{(\rho)(D/k_R)}\right](A_c/\bar{S}_0) \tag{33}$$

or

$$Q_R{}^*/\omega_c=K_3(A_c/\bar{S}_0) \tag{34}$$

where

$$K_3=\frac{\bar{B}_0}{(\rho)(D/k_R)} \tag{35}$$

Clearly from equation 28

$$M/\omega_c=2[(Q_T{}^*/Q_R{}^*)-\alpha](1/\pi) \tag{36}$$

The factor $(Q_T{}^*/Q_R{}^*)$ can be seen to be inherently independent of frequency by combining equations 7 and 9.

Thus

$$(Q_T{}^*/Q_R{}^*)=(K_1/K_2)(A_w/l) =(0.4A_w)(D/k_R)/(\bar{H}_0 l) \tag{37}$$

For purposes of this investigation, the change in $\bar{H}_0$ due to frequency is assumed negligible. In addition, since the change in $\bar{H}_0$ caused by changing ID/OD is normally no greater than the differences between samples of the same material, this factor is neglected.

At this point is is necessary to investigate the effect of α so as to be able to remove it as a variable. The ultimate objective of course is to reduce the expressions for output power, power gain, etc., to functions only of the physical dimensions and/or dimensional ratios of the toroidal core. In Fig. 3 the normalized output power, figure of merit, and steady-state power gain are plotted versus the normalized α. Clearly the condition for maximum $[(\overline{VA})_L/\omega_c]$ and maximum (M/ω_c) obtains when α is zero. Note that the maximum power-gain condition corresponds to $Q_c{}^*$ equal to one half of $Q_T{}^*$, i.e., the control winding occupies one half of the window area. Clearly a compromise value of α is necessary if it is to be eliminated as a variable. Quite naturally this value has been taken as

$$\alpha=(0.25)(Q_T{}^*/Q_R{}^*)$$

Thus, at this point, the important parameters $(\overline{VA}_L/\omega_c)$, (M/ω_c), and (G_p/ω_c) each has a value corresponding to 75% of the maximum attainable; i.e.,

$$(\overline{VA})_L/\omega_c=(0.75)[(\bar{B}_0\bar{H}_0)(V_c)(2)\times (Q_T{}^*/Q_R{}^*)],\ \alpha=(Q_T{}^*/Q_R{}^*)/4 \tag{38}$$

and

$$G_p/\omega_c=(0.25Q_T{}^*/Q_R{}^*)(Q_R{}^*/\omega_c)\times (0.75Q_T{}^*/Q_R{}^*)$$

or

$$G_p/\omega_c=(0.1875)(Q_R{}^*/\omega_c)(Q_T{}^*/Q_R{}^*)^2,\ \alpha=(Q_T{}^*/Q_R{}^*)/4 \tag{39}$$

Also

$$M/\omega_c=(0.75)[2(Q_T{}^*/Q_R{}^*)(1/\pi)],\ \alpha=(Q_T{}^*/Q_R{}^*)/4 \tag{40}$$

The subsequent work is such that any other finite value of α could have been selected with the same end result.

In the foregoing, the important parameters which describe magnetic-amplifier performance have been reduced to functions of two variables, namely $(Q_T{}^*/Q_R{}^*)$

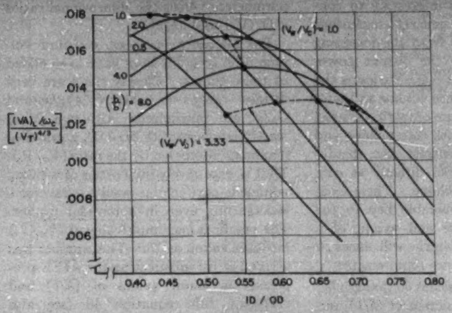

Fig. 4. Load power (normalized with respect to carrier frequency and total transformer volume) versus toroidal-core dimensional ratios h/b and ID/OD

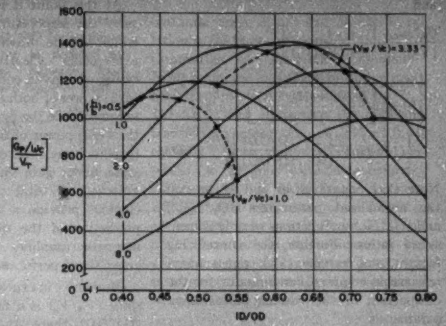

Fig. 5. Steady-state power gain (normalized with respect to carrier frequency and total transformer volume) versus toroidal-core dimensional ratios h/b and ID/OD

and (Q_R^*/ω_c). These two variables in turn are functions only of the physical dimensions of the core, i.e.,

$$(Q_T^*/Q_R^*) = (K_1/K_2)(A_w/l) \tag{37}$$

and

$$Q_R^*/\omega_c = K_2(A_c/\bar{S}_0) \tag{34}$$

It remains to reduce further (A_w/l) and $(A_c/\bar{S}_0)$ to more basic dimensions and/or dimensional ratios. It has been found that the most meaningful of these latter quantities are:

1. (ID/OD), the ratio of core inside diameter to outside diameter.
2. (h/b), the ratio of core height to build-up.
3. V_c, the volume of the core.
4. V_w/V_c, the ratio of winding volume to core volume.
5. V_T, the total volume of the wound core

Clearly, if an optimum core shape exists, this optimum should be independent of the physical size of the core. That is, those parameters which are descriptive of magnetic-amplifier performance should be reducible to functions of only dimensional ratios such that the absolute values of the dimensions merely act as scale factors to change the physical size but not the shape of the core. In line with this reasoning (Q_T^*/Q_R^*) and (Q_R^*/ω_c) are next normalized with respect to size, i.e., V_c and V_T, such that they become functions only of dimensional ratios. Thus using equation 27 and noting that

$$\frac{A_w}{l} = \left[\frac{V_c}{(\pi)(h/b)\left(\frac{1}{\text{ID/OD}}-1\right)^2\left(\frac{1}{\text{ID/OD}}+1\right)^4}\right]^{1/3} \tag{41}$$

it can be seen that

$$\frac{(Q_T^*/Q_R^*)}{(V_c)^{1/3}} = \frac{(K_1)}{(K_2)} \times \left[\frac{1}{(\pi)(h/b)\left(\frac{1}{\text{ID/OD}}-1\right)^2\left(\frac{1}{\text{ID/OD}}+1\right)^4}\right]^{1/3} \tag{42}$$

It has been found that the mean length of turn $(\bar{S}_0)$ of a winding which completely fills the window of a toroidal core is given with good approximation by

$$\bar{S}_0 = 2h \times \left\{1+\frac{(0.98)[(\text{ID/OD})+0.306]}{[1-(\text{ID/OD})](h/b)}\right\}, \quad \text{ID/OD} \leq 0.9 \tag{43}$$

(This expression was derived from a more general formulation of the mean length of turn of any winding on a toroid which was published in a Boeing Airplane Company internal memorandum by Louis Miovski.) Therefore, the use of equation 43 permits equation 34 to be reduced to the following

$$\frac{Q_R^*/\omega_c}{(V_c)^{1/3}} = \left\{\frac{(0.5)(K_2)}{(0.98)\left[\frac{0.306+(\text{ID/OD})}{1-(\text{ID/OD})}\right]+(h/b)}\right\} \times \left\{(1/\pi)(h/b)^2\left[\frac{1-(\text{ID/OD})}{1+(\text{ID/OD})}\right]\right\}^{1/3} \tag{44}$$

Since

$$V_T = V_c[1+(V_w/V_c)] \tag{45}$$

equations 42 and 44 can also be put in the form

$$\frac{Q_T^*/Q_R^*}{(V_T)^{1/3}} = \left(\frac{K_1}{K_2}\right)\left[\frac{1}{1+(V_w/V_c)}\right] \times \left[\frac{1}{(\pi)(h/b)\left(\frac{1}{\text{ID/OD}}-1\right)^2\left(\frac{1}{\text{ID/OD}}+1\right)^4}\right]^{1/3} \tag{46}$$

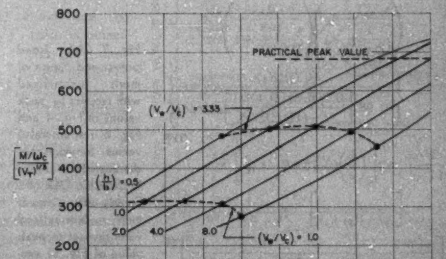

Fig. 6. Figure of merit (normalized with respect to carrier frequency and total transformer volume) versus toroidal-core dimensional ratios h/b and ID/OD

and

$$\frac{Q_R^*/\omega_c}{(V_T)^{1/3}}=\left[\frac{1}{1+(V_w/V_c)}\right]^{1/3}\times$$

$$\left\{\frac{(0.5)(K_3)}{(0.98)\left[\frac{0.306+(\mathrm{ID/OD})}{1-(\mathrm{ID/OD})}\right]+(h/b)}\right\}\times$$

$$\left\{(1/\pi)(h/b)^2\left[\frac{1-(\mathrm{ID/OD})}{1+(\mathrm{ID/OD})}\right]\right\}^{1/3} \tag{47}$$

Note that equations 46 and 47 present the normalized parameters (Q_T^*/Q_R^*) and (Q_R^*/ω_c) as functions of only dimensional ratios. Further, the normalizing factor, total volume (V_T), represents a reasonable common denominator for the comparison of the various performance parameters.

After some algebraic manipulation it is found that

$$\frac{V_w}{V_c}=\frac{(A_w\bar{S}_0)}{(bhl)}=2\times$$

$$\left\{\frac{(0.98)\left[\frac{0.306+(\mathrm{ID/OD})}{1-(\mathrm{ID/OD})}\right]+(h/b)}{\left(\frac{1}{\mathrm{ID/OD}}+1\right)\left(\frac{1}{\mathrm{ID/OD}}-1\right)(h/b)}\right\} \tag{48}$$

and

$$V_c=(h^3)\left\{\frac{(\pi)[1+(\mathrm{ID/OD})]}{(h/b)^2[1-(\mathrm{ID/OD}]}\right\} \tag{49}$$

Using equations 45, 48, and 49 and the expressions in equations 46 and 47, equations 38 through 40 can be reduced to functions of dimensional ratios only Thus,

$$\frac{(\overline{VA})_L/\omega_c}{(V_T)^{4/3}}=2[(0.75)(\bar{B}_0\bar{H}_0)(K_1/K_2)]\times$$

$$\left[\frac{1}{1+(V_w/V_c)}\right]^{4/3}\times$$

$$\left[\frac{1}{(\pi)(h/b)\left(\frac{1}{\mathrm{ID/OD}}-1\right)^2\left(\frac{1}{\mathrm{ID/OD}}+1\right)^4}\right]^{1/3} \tag{50}$$

$$\frac{G_p/\omega_c}{V_T}=[(0\ 06)(K_1/K_2)^2]\left[\frac{1}{1+(V_wV_c)}\right]\times$$

$$\left(\frac{1}{\frac{1}{\mathrm{ID/OD}}-1}\right)\left(\frac{1}{\frac{1}{\mathrm{ID/OD}}+1}\right)^3\times$$

$$\left\{\frac{(0.5)(K_3)}{(0.98)\left[\frac{0.306+(\mathrm{ID/OD})}{1-(\mathrm{ID/OD})}\right]+(h/b)}\right\} \tag{51}$$

$$\frac{M/\omega_c}{(V_T)^{1/3}}=2\left[\left(\frac{1}{\pi}\right)(0.75)(K_1/K_2)\right]\times$$

$$\left[\frac{1}{1+(V_w/V_c)}\right]^{1/3}\times$$

$$\left[\frac{1}{(\pi)(h/b)\left(\frac{1}{\mathrm{ID/OD}}-1\right)^2\left(\frac{1}{\mathrm{ID/OD}}+1\right)^4}\right]^{1/3} \tag{52}$$

At this point it is interesting to consider the important general conclusions which can be drawn from the foregoing expressions. Clearly the output power rating of a given core shape varies as the (4/3) power of both core volume and total volume, while the figure of merit varies as the (1/3) power of both core volume and total volume. In contrast, the steady-state power gain varies directly as core volume and total volume. These conclusions provide a valuable key to the prediction of the size and weight of a magnetic amplifier which will meet a given set of performance requirements.

Obviously, in expressions 50 through 52, since (V_w/V_c) is a function of (h/b) and (ID/OD), there are only two variables, namely, (h/b) and (ID/OD). Note that (K_1/K_2) and K_3, which are dependent on the kind of core material, allowable current density, etc., are merely scale factors which can have no effect on the shape of the curves for the foregoing three expressions. Therefore, for simplicity, typical values for K_1/K_2, K_3, and $\bar{B}_0\bar{H}_0$ have been utilized in the following (see the Appendix). Figs. 4 through 6 respectively present plots of the three performance parameters versus the dimensional ratios (ID/OD) and (h/b).

For reference purposes, constant volume ratio (V_w/V_c) lines have been added to these curves. Clearly there are very definite ranges in which $(\overline{VA})_L/\omega_c$ and G_p/ω_c are maximized. Although M/ω_c merely increases with ID/OD, a practical maximum is imposed by the ratio (V_w/V_c). That is, excessively high ratios of winding volume to core colume results in excessive leakage flux even in a toroidal reactor. The practical maximum value of (V_w/V_c) has been taken as 15. This number was arrived at by substituting the AIEE proposed maximum values of (h/b) and (ID/OD) into equation 48 (see also Fig. 9).

The peak values can be determined from the three curves to be:

$$\text{Peak}\left|\frac{(VA)_L/\omega_c}{(V_T)^{4/3}}\right|=0.018$$

$$\text{Peak}\left|\frac{G_p/\omega_c}{(V_T)}\right|=1,420$$

$$\text{Peak}\left|\frac{M/\omega_c}{(V_T)^{1/3}}\right|=682$$

If each of the curves (Figs. 4 through 6)

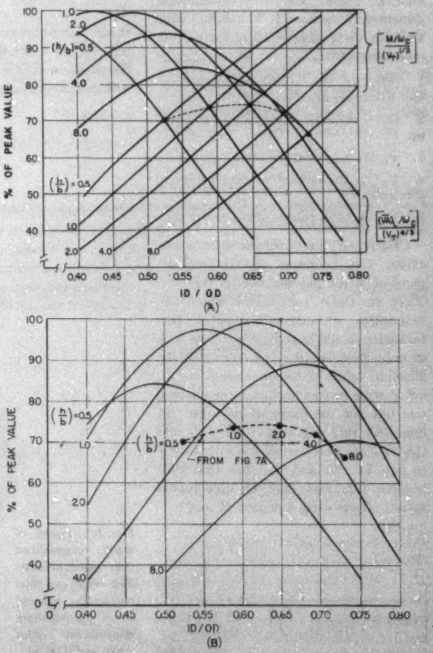

Fig. 7 (A). Load power and figure of merit (normalized with respect to peak values of Fig. 4 and Fig. 6 respectively) versus toroidal-core dimensional ratios h/b and ID/OD. (B). Steady-state power gain (normalized with respect to peak value of Fig. 5) versus the toroidal core dimensional ratios h/b and ID/OD

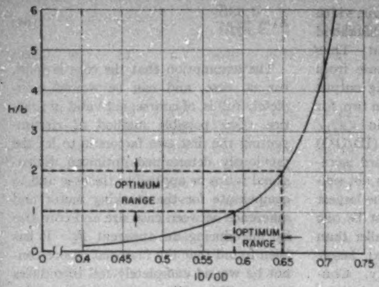

Fig. 8. Relationship between h/b and ID/OD for optimum toroidal core as dictated by compromise between load power and figure of merit

is normalized with respect to the appropriate peak value, the plots in Fig. 7 result. These plots permit the selection of those dimensional ratios which represent the best compromise between all three key performance parameters. If $(\overline{VA})_L/\omega_c$ and M/ω_c are weighed as being of equal importance, then the intersections of the appropriate normalized curves, Fig. 7(A), represent a compromise between these two factors. Fortunately these intersections, Fig. 7(B), occur very near the peak values for the corresponding G_p/ω_c. Therefore, under compromise conditions, both $(\overline{VA})_L/\omega_c$ and M/ω_c are reduced to approximately 70% to 75% of their peak values, and G_p/ω_c is approximately 90% of the peak value in the ID/OD range between approximately 0.55 and 0.70. The analytical solution for the intersection of the $(\overline{VA})_L/\omega_c$ and the M/ω_c curves corresponds to a constant (V_T/V_c) ratio of 3.33 which (using equation 48 can be reduced to

$$(h/b) = \left[\frac{(0.98)[0.306+(\mathrm{ID/OD})]}{[1-(\mathrm{ID/OD})]\left[(1.667)\times\left(\frac{1}{\mathrm{ID/OD}}+1\right)\left(\frac{1}{\mathrm{ID/OD}}-1\right)-1\right]}\right] \tag{53}$$

This expression is plotted in Fig. 8 and clearly illustrates that a reasonable compromise between output power and figure of merit is impossible for values of ID/OD greater than 0.7 if the practical maximum value of h/b is taken as four. The relationship in equation 53 is the key to the subsequent selection of optimum standard core sizes.

The ratio of winding volume to core volume (V_w/V_c) is obviously a very important parameter in view of the fact that the locus of the compromise values of (ID/OD) and (h/b) corresponds to a constant volume ratio of 3.33. It is also interesting to note that the locus of the peak values of normalized output power (Fig. 4) corresponds to a constant (V_w/V_c) ratio of one. Although in the magnetic amplifier it is undesirable to optimize the load power at the expense of power gain and figure of merit, such an optimization is possible in a simple transformer. Thus a (V_w/V_c) ratio of one is ideal for toroidal transformers and the relationship between (h/b) and (ID/OD) would properly be

$$h/b = \left[\frac{(0.98)[0.306+(\mathrm{ID/OD})]}{[1-(\mathrm{ID/OD})]\left[(0.5)\times\left(\frac{1}{\mathrm{ID/OD}}+1\right)\left(\frac{1}{\mathrm{ID/OD}}-1\right)-1\right]}\right] \tag{54}$$

In the opinion of the authors, the 25% reduction in output power and figure of merit which obtains under compromise conditions is not sufficient to warrant the selection of two classes of core sizes, i.e., high power versus high gain, for magnetic-amplifier application. However, equation 54 could be used as the basis for the selection of optimum toroidal transformer cores.

A study of Fig. 7(A) reveals that, as long as the proper V_w/V_c ratio is maintained, both (h/b) and (ID/OD) can vary over a wide range with but little effect on the values of $(\overline{VA})_L/\omega_c$ and M/ω_c. However, very definite optimum ranges for these parameters are dictated, Fig. 7(B), by the steady-state power gain G_p/ω_c. Note that in the h/b range between one and two, G_p/ω_c is approximately 95% of the peak value but that it falls off rapidly for large and for smaller values of h/b. In view of this and also in view of the practical limitations on the value of h/b, the h/b range between one and two has been selected as optimum. Fig. 9 serves to clarify the location of the optimum range of h/b and ID/OD in relation to the limits proposed by the AIEE Committee on Magnetic Amplifiers.[8] In addition, the location of optimum magnetic-amplifier cores (determined by $V_w/V_c=3.33$) with respect to the optimum transformer cores, i.e., $V_w/V_c=1.0$, is clarified. Note that the common criterion for the good toroidal transformer core, namely a unity ratio between window area and core area (A_w/A_c), corresponds very roughly to a V_w/V_c of one. However, in the opinion of the authors, the latter parameter is a better measure of the performance to be expected from a toroidal transformer.

Proposed Standard Core Sizes

The utilization of the foregoing information in a logical manner can yield a list of optimum shaped cores which effectively covers the practical range of sizes. The output power capacity of the core $(\overline{VA})_L/\omega_c$ has been selected as the parameter which determines the size of the steps between core sizes. After the fashion of wire sizes, it has been decided to arrange standard cores in the order of increasing power on a logarithmic scale. Therefore, it is proposed to have ten cores for each order of magnitude of output power rating, with the even-numbered cores being preferred sizes. It is further intended to utilize the proposed AIEE standard tape widths. The fact that it is impossible to also utilize only the proposed standard inside diameters can be verified by noting that

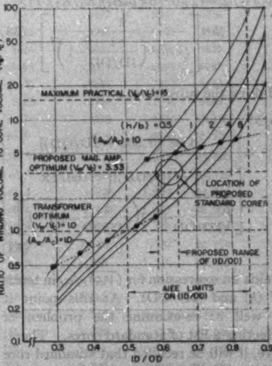

Fig. 9. Ratio of winding volume to core volume versus toroidal-core dimensional ratios h/b and ID/OD, illustrating location of proposed optimum standard toroidal cores

$$\frac{\mathrm{ID}}{h}=\left[\frac{2}{(h/b)\left(\dfrac{1}{\mathrm{ID/OD}}-1\right)}\right] \tag{55}$$

Clearly if both ID and h are only standard sizes, the relationship between (h/b) and (ID/OD) is predetermined and the optimum condition described by equation 53 cannot be utilized. Therefore, if either (ID) or (h) is to be standardized, the other must be allowed to have nonstandard values. In the opinion of the authors, standard values of tape width (h) are very desirable while nonstandard ID represent only a minor inconvenience. Of course, this opinion could lead to a philosophical argument about the relative merits of complete standardization on a minimum number of standard dimensions versus the resultant compromised performance of the toroidal core. It is felt that at this stage in the growth of magnetic amplifiers, an unreasonably restrictive standardization is unrealistic. When one compares the added complexity introduced by nonstandard ID to the present lack of standardization in the vacuum-tube field, the former factor seems quite insignificant.

To evaluate $(\overline{VA})_L/\omega_c$, equation 38 can be reduced (by using equation 37) to

$$(\overline{VA})_L/\omega_c=2[(0.75)(\overline{B}_0\overline{H}_0)(K_1/K_2)]\times(A_cA_w) \tag{56}$$

where

$$(A_cA_w)=(h^4)\left[\frac{\pi}{(h/b)^3\left(\dfrac{1}{\mathrm{ID/OD}}-1\right)^2}\right] \tag{57}$$

From this, it can be seen that

$$(\overline{VA})_L/\omega_c=(2)(0.75)(B_0H_0)(K_1/K_2)(\pi)\times(h^4)\left[\frac{1}{(h/b)^3\left(\dfrac{1}{\mathrm{ID/OD}}-1\right)^2}\right] \tag{58}$$

Making the substitution

$$(h/b)=\left[\frac{(0.98)[0.306+(\mathrm{ID/OD})]}{[1-(\mathrm{ID/OD})]\left[(1.667)\times\left(\dfrac{1}{\mathrm{ID/OD}}+1\right)\left(\dfrac{1}{\mathrm{ID/OD}}-1\right)-1\right]}\right] \tag{53}$$

yields an expression for $(\overline{VA})_L/\omega_c$ in terms of (h) and (ID/OD). At this point it is well to re-examine the problem of selecting a list of standard cores. Therefore, it will be recalled that standard core heights ($^1/_8$, $^1/_4$ inch, etc.) must be utilized and (ID/OD) must be kept in the optimum range which falls approximately between 0.575 and 0.675 (see Fig. 9). Further, it has been arbitrarily decided that the largest core of a given tape width should have an h/b in the neighborhood of one, i.e., square cross section. Thus (h/b) will be allowed to increase from one (in the process of changing output power) rather than decrease from two, for example. Further, the increase in $(\overline{VA})_L/\omega_c$ which obtains for a constant (ID/OD) when (h) is increased in standard increments ($^1/_8$, $^3/_{16}$, $^1/_4$ inch, etc.) is not uniform, therefore, the fact that the largest core of a given height (h) must be one increment of output power smaller than the smallest core of the next larger height, leads to some difficulty. Consideration of all these factors makes the analytical solution of equation 58 rather tedious. It has been found that a graphical solution is more straightforward.

Inherent in equations 50 through 52 is the assumption that the control winding occupies one fourth of the window area, i.e., $\alpha=(Q_T^*/Q_R^*)/4$. Since the actual value of α merely acts as a scale factor on the absolute value of output power, etc., it has no effect on the previous optimization process based on normalized values (Fig. 7). However, it is desirable, in the tabulation of core parameters, to itemize the maximum attainable values of $(\overline{VA})_L/\omega_c$, M/ω_c, and G_p/ω_c. Therefore, since each of these quantities has 75% of its maximum value in equations 50 through 52 it is a simple process to determine these maximums. In addition, it is desirable to so generalize the tabulation as to make it independent of the characteristics of the core material, and the allowable current density, etc. Therefore, equations 50 through 52 can be modified to yield

$$\max[(\overline{VA})_L/\omega_c](K_4)=(V_c)^{4/3}\times\left[\frac{1}{(h/b)\left(\dfrac{1}{\mathrm{ID/OD}}-1\right)^2\left(\dfrac{1}{\mathrm{ID/OD}}+1\right)^4}\right]^{1/3} \tag{59}$$

$$K_4=\frac{2.03}{(D)(\overline{B}_0)} \tag{60}$$

$$\max(G_p/\omega_c)(K_5)=(V_c)\times\left(\frac{1}{\dfrac{1}{\mathrm{ID/OD}}-1}\right)\left(\frac{1}{\dfrac{1}{\mathrm{ID/OD}}+1}\right)^2\times\left\{(0.98)\left(\frac{0.306+(\mathrm{ID/OD})}{1-(\mathrm{ID/OD})}\right)+(h/b)\right\} \tag{61}$$

$$K_5=\left(\frac{176\rho}{D}\right)\left[\frac{\overline{H}_0}{(\overline{B}/\overline{H}_0)}\right] \tag{62}$$

$$\max(M/\omega_c)(K_6)=(V_c)^{1/3}\times\left[\frac{1}{(h/b)\left(\dfrac{1}{\mathrm{ID/OD}}-1\right)^2\left(\dfrac{1}{\mathrm{ID/OD}}+1\right)^4}\right]^{1/3} \tag{63}$$

$$K_6=\frac{6.38\overline{H}_0}{D} \tag{64}$$

The assumption that the core is solid, has no case, and can be wound completely full is, of course, not valid in practice. One possible method of circumventing the first two factors is to let the previously determined optimum dimensional ratios be applied to the case and to compensate for the stacking factor and difference between case size and core size by introducing an apparent $\overline{B}_0$. It has been found that the fact that a core cannot be wound completely full introduces a nonuniform discrepency between the idealized and the practical results. This latter factor is virtually impossible to generalize because of the differences between the capabilities of different winding machines. It has been arbitrarily decided to select standard cores on the basis of the idealized solid core with no case and subsequently to tabulate the resultant practical values of the various parameters of interest.

It is interesting to note that equation 56 indicates that the power rating of a core is proportional to the product of core area and window area as has been previously indicated in the report of the AIEE Committee on Magnetic Amplifiers.[3] This one factor (A_cA_w) of course does not yield sufficient information to permit the selection of optimum core configurations.

The proposed list of standard cores appears in Table I. The tabulated 63 cores cover more than six orders of magnitude of normalized output power $(\overline{VA})_L/\omega_c$.

After the fashion of wire tables, a logarithmic scale has been used such that there are ten cores per decade of power. Therefore, an increase of three core sizes doubles the power rating, an increase of ten core sizes increases the rating by a factor of ten, etc. This uniformity in the core sizes should prove to be a great aid in the simplification of magnetic-amplifier design. In addition to the uniform increments of power between core sizes, the other parameters, power gain, and figure of merit also vary in a uniform manner. For example, since the output power varies as the (4/3) power of total volume and the figure of merit varies as the (1/3) power of total volume, it can be seen that figure of merit varies as the (1/4) power of output power. Thus the figure of merit increases by $(2)^{1/4}$ or a factor of 1.19 for each increase of three core sizes. Likewise the power gain increases by $(2)^{3/4}$ or a factor of 1.68 for each three core sizes. It is proposed, again after the

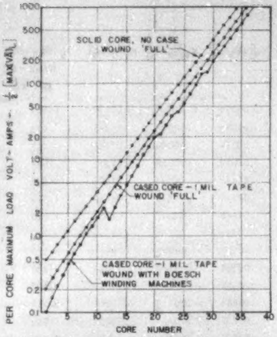

Fig. 10. Idealized maximum output power and practical maximum output power for proposed standard toroidal cores

fashion of wire tables, that the even-numbered cores be preferred sizes.

For illustration purposes, max $[(\overline{VA})_L]$ has also been tabulated for each core in Table I at a frequency of 1,000 cycles per second using typical Hymu-80 core material and the previously mentioned allowable current density. The difference between this theoretical limit and the output power attainable from a practical core (with core box, stacking factor, and minimum hole ID introduced) is illustrated by Fig. 10. Note that if the practical core can be wound completely full, i.e., no hole, a smooth curve results, but that the introduction of the practical limitations of typical winding machines produces a nonuniform difference between theoretical and practical results.

Applicability to Half-Wave Magnetic Amplifiers

The fact that the foregoing is also valid for half-wave circuits can be seen by noting that the load circuit, and therefore output power, considerations are the same. In addition, the steady-state power gain and the figure of merit differ only by a constant (π/ω_c) such that the previous compromise between output power and figure of merit is still valid.

Conclusions

An analytical method has been presented whereby the effect of toroidal-core dimensional ratios (h/b and ID/OD) on three major magnetic-amplifier performance parameters can be evaluated. On the basis of this evaluation, the optimum functional relationship between these dimensional ratios, in addition to the optimum range of values for the ratios, has been determined. Utilizing the foregoing information, a list of proposed standard cores which uniformly covers the practical range of sizes has been presented.

Appendix. Typical Values for the Constants (K_1/K_2),(K_3), and $(\bar{B}_0\bar{H}_0)$

For illustration purposes a typical toroid utilizing Hymu-80 core material has been selected. It is assumed that:

1. The winding temperature is 25 degrees centigrade such that $\rho=6.79\times10^{-7}$ ohm-inch.
2. The maximum allowable current density is $D=2{,}546$ amperes per square inch (or 2 milliamperes per circular mil).
3. The form factor of the reset current is $k_R=1.0$.
4. The average flux density is $\bar{B}_0=2.645\times10^{-4}$ webers per square inch (or 0.41 webers per square meter).
5. The average magnetizing force is $\bar{H}_0=0.1372$ ampere-turn per inch (or 5.4 ampere-turns per meter).

Therefore,

$$|K_1/K_2|=\frac{0.4(D/k_R)}{\bar{H}_0}=7{,}430$$

and

$$|K_3|=\frac{\bar{B}_0}{\rho(D/k_R)}=0.153$$

Also,

$$|\bar{B}_0\bar{H}_0|=3.63\times10^{-5}$$

Discussion

Edward Korn (Aerophysics Development Corporation): While the authors' statement that "the change in H_0 caused by changing ID/OD is normally no greater than the differences between samples of the same material" may be true, it does not necessarily follow that this factor is negligible. Certainly the general trend is to higher permeabilities as ID/OD is increased regardless of the variations from core to core. Also, it would seem that the authors have neglected the possibility of winding two stacked cores with common control windings in their development of optimum core shapes.

R. M. Hubbard and **M. M. Bishop**: Mr. Korn's first point is well taken. Originally it was felt that too little was known of the effect of ID/OD ratio, especially of the manner in which it varied with core material, to permit its inclusion in a generalized investigation. However, an effort has subsequently been made to add this factor to the study.

The main source of information on the manner in which the ID/OD ratio affects the dynamic performance of the core is contained in a paper by Roberts and Van Nice[1] and in a paper by Brownell.[2] These papers provide information which is applicable to one class of magnetic material, namely, grain-oriented 50% NiFe. In order to illustrate the manner in which this factor would modify the results of this particular investigation, it is necessary to introduce the concept of threshold magnetizing force $(\bar{H}_t)$ which was originally neglected in defining $\hat{R}$ as the slope of the line from the origin to the knee of the magnetization curve. This is due to the fact that, although the average magnetizing force corresponding to full reset $(\bar{H}_0)$ is substantially invariant with ID/OD, the average threshold magnetizing force $\bar{H}_t$ varies considerably (for 50% Ni-Fe). The introduction of $\bar{H}_t$ invalidates the use of the a-c magnetization curve to define $\hat{R}$ and requires the use of the type of curve obtained on some sort of adjustable reset core tester such as that described by Roberts.[3] The net result is that, in equations 59 through 64, the quantity $(\bar{H}_0-\bar{H}_t)$ must be substituted for $\bar{H}_0$ alone. Since changes in $(\bar{H}_0-\bar{H}_t)$ are inversely proportional to changes in differential permeability (as ID/OD ratio is changed), it can be seen that the constants K_3 and K_6 become variables with ID/OD. As a result, the functional relationships between ID/OD ratio and both normalized power gain and figure of merit are changed. These modified relationships, illustrated by Figs. 11 and 12, have been developed by making use of the functional relationship between differential permeability and ID/OD ratio (see Fig. 13) which is suggested in reference 1. The changes introduced by Figs. 11 and 12 are clarified by taking note of the original figures, Figs. 7(A) and (B) of the text. The new optimum functional relationship between h/b and ID/OD dictated by a compromise between load volt-amperes and figure of merit is depicted

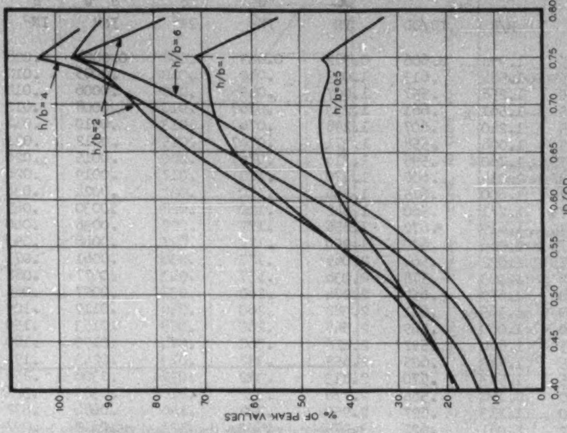

Fig. 11 (left). Load power and figure of merit (normalized) versus toroidal-core dimensional ratios h/b and ID/OD

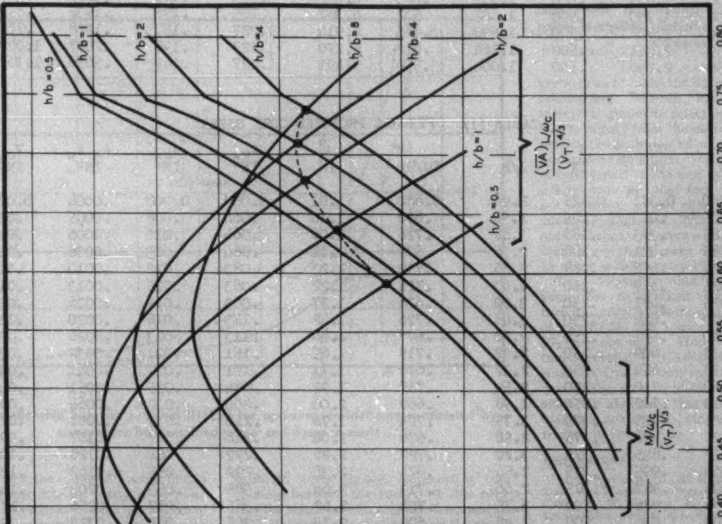
Fig. 12 (above). Steady-state power gain (normalized) versus toroidal-core dimensional ratios h/b and ID/OD



in Fig. 14. The optimum ranges of the variables have been selected by taking note of the shape of the power-gain curve of Fig. 12.

It should be noted that the new optimum relationship between *h/b* and ID/OD (Fig. 14) is not radically different from the original one. The major difference is in the optimum ranges of ID/OD and *h/b*. Thus, the optimum range for *h/b* is shifted from the original range between one and two to the new range between two and four. One might conclude that optimum cores could logically fall anywhere between the two curves and that added emphasis on that variable involving change in permeability with ID/OD merely serves to shift the optimum ranges to higher *h/b* and higher

ID/OD. Thus, the important result of this extension of the original study is to point out that, if one wishes to take advantage of the increased permeability associated with the higher ID/OD ratios, he should also utilize the higher h/b ratios dictated by the optimum functional relationships of Fig. 14. Clearly, in view of the many unresolved questions associated with the relationship between the differential permeability of various materials and ID/OD ratio, a reasonable proposal for optimum standard cores should represent a compromise between the results of this study and the results of the original investigation.

To illustrate the application of the results presented in Fig. 14, two lists of possible optimum-shaped cores have been compiled. The first list (Table II) is based on the original optimum range of h/b between one and two but does not represent a rigid adherence to the original curve of Fig. 14. By adopting the practical point of view that the assumptions inherent in this analysis are such as to make the optimum functional relationship between h/b and ID/OD merely a guide in selecting cores, one is free to depart from the optimum such as to permit the inclusion of more standard ID in the core tabulation. Table III is a listing of cores based on the new optimum range of h/b between two and four and it too does not represent a rigid adherence to the new curve of Fig. 14. The location of the optional standard cores with reference to the original proposed cores is clarified by Fig. 15 which is taken from Fig. 9.

The observation that this study is not applicable to stacked cores is partially true in that the results pertaining to figure of merit (M) and steady-state power gain (G_p) are not valid. However the information associated with load power rating $(\bar{V}\bar{A})_L$ is valid. One can only say that this analysis covers the most typical core applications since it is also clear that saturable reactors, magnetic modulators, etc., are not explicitly treated in this paper.

A Power Method of Measuring the Torque-Producing Output of a Magnetic Amplifier Driving One Phase of a Two-Phase Servo Motor

S. J. REISMAN
NONMEMBER AIEE

E. H. BOWMAN
NONMEMBER AIEE

THE purpose of this paper is to describe a "power" method of measuring the useful, torque-producing component of the a-c output voltage from magnetic amplifiers used in applications wherein the output phase angle is important, and wherein the ideal phase angle, with respect to the amplifier's excitation, is either zero degree or 90 degrees. Typical of such applications is a single-phase amplifier used to drive one phase of a 2-phase servo motor.

In this specific application, when only single-phase power is available, the phase to one or both windings of the motor must be shifted to arrive at quadrature voltages across the windings. Usually, the phase shift is applied to one circuit only and, depending on where the phase shift is accomplished, the ideal phase angle at the output of the amplifier, with respect to the line voltage, is either zero degree or 90 degrees.

Assume that the voltage across the reference winding is held constant, that the line frequency is held constant, that the line voltage has a negligible harmonic content, and that voltages are held to those values producing motor torque within its linear range. Then the expression for the stall torque of the motor may be written

$$T = KE \sin \theta \qquad (1)$$

where T is the stall torque, K is a constant of proportionality, E is the fundamental component of voltage across the motor control winding and θ is the phase angle between the voltages on the two windings. Equation 1 may also be written

$$T = KE \sin (\pi/2 + \phi) \qquad (2)$$

where ϕ is the angle of deviation from 90 degrees.

Fig. 1 is a plot of control phase voltages which yield torques lying between the arbitrarily selected limits of T_1 and T_2 (where $T_2 = 2T_1$) against respective phase angles (as deviations from $\pi/2$). Within the area bounded by the two curves of constant torque and E_{max}, there is also a 2 to 1 ratio of permissible voltage limits for every value of ϕ, except where E_{max} imposes a limit on the maximum voltage.

E_{max} is a limit arbitrarily imposed; but is practical by virtue of two considerations. First, there is a limit to the voltage which may safely be impressed across the motor winding, regardless of the magnitude of error in the servo loop (this limit is practically achieved by the saturation of the amplifier). Second, there is some maximum value (presumably, considerably less than $\pi/2$) to which ϕ should be held in any well-designed amplifier.

Consider two methods of imposing limits on the static transfer characteristic of the amplifier:

1. Voltage and phase angle may be measured separately, with noninterdependent limits imposed on both.
2. Voltage and phase angle may be measured (individually or in combination) and limits imposed on torque.

In Fig. 1, the effect of the limits imposed by method 1 is graphically presented. The figure shows arbitrarily selected limits for ϕ of $\pm\pi/4$. Since limits of voltage must be established to accommodate any value of ϕ between the limits of $\pm\pi/4$, the upper limit E_2 must be established for $\phi = 0$ and the lower limit E' for $\phi = \pi/4$. Thus, only those amplifiers whose characteristics lie within the limits imposed by the rectangle bounded by $\pm\pi/4$, E' and E_2 may be accepted. It is apparent that, for given torque limits, the wider the limits allowed for ϕ the smaller must be the ratio of E_2 to E', or

$$\frac{T_2}{T_1} = \frac{E_2 \sin \pi/2}{E' \cos \phi_{max}} \text{ and } \frac{E_2}{E'} = \frac{T_2 \cos \phi_{max}}{T_1} \qquad (3)$$

By method 2, E (the permissible voltage) may be as small as E_1 or:

$$E = \frac{T_1}{K \sin \pi/2} = \frac{T_1}{K} \qquad (4)$$

and, for a maximum value for ϕ of $\pi/4$, E may be as large as E''.

$$E = E'' = \frac{T_2}{K \sin (\pi/2 \pm \pi/4)} = \frac{T_2}{K \cos \pi/4} \qquad (5)$$

Thus, for the above limits for ϕ, amplifiers whose characteristics lie within the limits of the cross-hatched areas lying above and below the rectangle are acceptable.

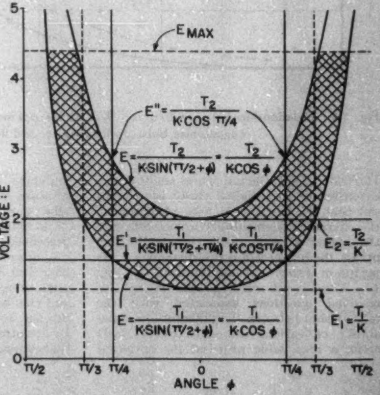

Fig. 1. Loci of $KE[\sin(\pi/2+\phi)]$ for two values of constant torque ($T_2 = 2T_1$)

Paper 58-897, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 11, 1958; made available for printing April 17, 1958.

S. J. REISMAN is with the Westinghouse Electric Corporation, East Pittsburgh, Pa., and E. H. BOWMAN is with the Sandia Corporation, Albuquerque, N. Mex.

Since, in general, to hold the torque within the limits of T_1 and T_2, E may have any value which satisfies the limiting equations of

$$E=\frac{T_1}{K\cos\phi} \text{ and } E=\frac{T_2}{K\cos\phi} \qquad (6)$$

it follows that, for wider permissible tolerances on ϕ, some of the cross-hatched areas lying beyond the limits of $\pm\pi/4$ would be within the acceptance limits.

For instance, if the tolerance limits on ϕ were $\pm\pi/3$, all amplifiers whose characteristics lie within the cross-hatched areas limited by the vertical dashed lines would be acceptable.

The additional quantity of amplifiers accepted by method 2 and rejected by method 1 may be relatively insignificant; or it may be appreciable. This depends on the distributions, around their respective means, of E and ϕ, and on what percentage of the total quantity of production amplifiers has characteristics which lie within the limits of E and ϕ required, by method 1, to satisfy the limits placed on torque.

For instance, assume that the distributions of both voltage and phase fit gaussian distribution curves; then if the limits of both voltage and phase imposed by method 1 embrace three standard deviations, any additional quantity of amplifiers accepted by method 2 would be relatively insignificant. On the other hand, if one or both were to embrace two standard deviations or less, such additional quantity might be appreciable. Obviously, it is the function (cos ϕ) and not the angle (ϕ) which is of direct interest; but it is highly improbable that the distribution of cos ϕ could, by any practical amplifier design, be made to fit a gaussian distribution curve.

Whatever may be the resultant advantages of method 2 with respect to raising the test acceptance level of production amplifiers, it offers other advantages. The high degree of distortion in the a-c output voltage of most magnetic amplifiers poses a difficult problem regarding the measurement of such voltage with any degree of accuracy. Filters and/or harmonic analyzers may be resorted to, but this poses the problem of phase shift through such instruments, which may change the shape of the voltage waveform. The nuisance value of harmonics is particularly great in servo amplifiers when measuring in the null region. However, direct measurement of the "effective" voltage can be accomplished by the use of a wattmeter type instrument. Thus, the voltage and phase are effectively measured "in combination", limits imposed are directly related to torque limits by equations 1 and 2, and method 2 is applicable. Additionally, it is possible, by method 2, to obtain a more accurate measurement of null output. The practical limitation of mismatch (in cores, turns, resistors, and rectifiers) dictates that the combined harmonic output voltage of push-pull magnetic amplifiers at the null of the fundamental is never zero. However, motor torque passes through zero with the fundamental voltage if no harmonics are present in the reference winding, and this is indicated by the wattmeter.

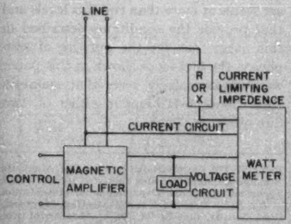

Fig. 2. Block diagram of a power-measuring circuit for a magnetic amplifier

The "power" method of measuring torque employs a reference current, representative of motor reference winding voltage, which is fed directly from the line supplying the magnetic amplifier through a limiting impedance (resistive or capacitive) and through the current circuit of a wattmeter, as shown in Fig. 2. The voltage circuit of the instrument is fed from the output of the magnetic amplifier, which is terminated into its rated load. Calibration of the instrument is accomplished by feeding both of the instrument's circuits from the line.

Actual measured values of power are, of course, functions of the reference current. Since a wattmeter reads EI cos ϕ (where ϕ is the phase angle between the voltage and current), it is necessary that the type of current-limiting impedance be chosen to match the nominal phase angle of the amplifier's output voltage with respect to the line. Hence, if the amplifier's output is nominally in quadrature with the line the reference current is fed through a capacitor; and if the amplifier's output is nominally in phase with the line the reference current is fed through a resistor. When measuring the phase-reversible output of a push-pull amplifier, provisions must be made for reversing the connections of either the current or voltage circuit of the meter as the amplifier's output reverses phase, in order that the meter will not read downscale.

In an actual application, power is supplied to both the magnetic amplifier and the motor reference winding from a 115-volt 400-cps (cycles per second) line, and the phase shift is effected in the amplifier. Fig. 3 is a block diagram of the circuit used to test this amplifier. The "load" represents the impedance of the motor control winding. It is significant that this method permits adjustment of the "load" impedance to the actual nominal impedance of the motor control winding, and also permits variation of such "load" to the tolerance limits of motor control winding impedance. This is especially pertinent in this particular application, where the phase shift is accomplished in the amplifier, since the amplifier's phase shifting network makes the phase and amplitude of the amplifier's output voltage more sensitive to variations in load impedance than would otherwise be the case.

The nominal carrier phase shift of ±90 degrees through the amplifier necessitates the use of a capacitor, rather than a resistor, to limit the wattmeter's reference current. The value of the capacitor is set at 0.2075 μf (microfarad), limiting the current (at 115 volts 400 cps) to 60 ma (milliamperes), which is the rating of the wattmeter's current circuit. To calibrate the meter, a resistance of 1,917 ohms is substituted for the capacitor, and both the voltage and current circuits of the meter are connected to the line. Thus, reference "power" (which is reference torque times a constant of proportionality) is

$$W=EI\cos\phi=(115 \text{ volts})(0.060 \text{ ampere})(1)=6.9 \text{ watts} \qquad (7)$$

For calibration at other points, the reference current should be held constant (to duplicate the conditions for use of the

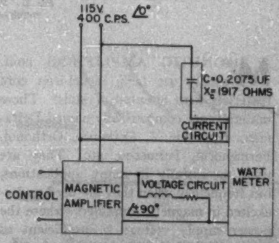

Fig. 3. Block diagram of a power-measuring circuit for a specific magnetic amplifier with quadrature voltage at the amplifier output

instrument) and the potential across the wattmeter's voltage circuit varied. Thus, the wattmeter reading becomes a linear function of the varying voltage. A check for zero power indication should be made by substituting the capacitor for the resistor.

Then, with the meter's current circuit connected through the capacitor, the amplifier terminated into its "load," the voltage circuit of the wattmeter connected across the "load," and reference current (at 115 volts 400 cps) fixed at 60 ma, the wattmeter's "power" reading will be proportional to the fundamental output voltage of the amplifier times the cosine of the phase angle (nominally zero) between this voltage and the reference current. The torque, then, is the wattmeter reading times a constant of proportionality.

$$T=KW=KE\cos\phi \qquad (8)$$

The fundamental output voltage of the magnetic amplifier is the wattmeter reading divided by the product of the reference current and the cosine of the phase angle

$$E=\frac{W}{0.06\cos\phi} \qquad (9)$$

and the "effective voltage" (which is $E\cos\phi$) is the wattmeter reading divided by the reference current

$$E_{eff}=\frac{W}{0.06} \qquad (10)$$

Thus, the true value of torque-producing voltage can be calculated, see equation 10, and this times a constant of proportionality yields the value of torque, as determined by the carrier phase shift through the amplifier and the amplifier's fundamental output voltage, which in turn depends upon the amplifier's control input and voltage gain.

The input impedance of the wattmeter's voltage circuit must be high enough to avoid a loading effect on the amplifier; the current sensitivity must be high enough to avoid loading the line beyond its capabilities; and, in the case of a capacitor as the limiting impedance, the resistance of the current circuit must be low enough, relative to the capacitive reactance, that the power factor of the circuit is not appreciable. A power factor of 0.01 at 400 cps is practicable. In the case of resistance current-limiting, a minimum power factor of 0.99 at 400 cps should be attainable without difficulty. The instrument used in the above application has a current circuit resistance at the 60-ma level of 0.75 ohm, and the input impedance of the voltage circuit is 1 megohm of resistance shunted by 25 micromicrofarads.

If it is desired to measure the transfer characteristic of the amplifier under variations in line voltage and/or frequency, the reference current must be adjusted for each condition, or limits of the transfer characteristic must be adjusted to accommodate for variation of the reference current with variations in line voltage and (in the case of capacitor current-limiting) frequency.

There are, of course, electromechanical methods of measuring the torque-producing output voltage of an a-c magnetic servo amplifier and, in applications where the phase angle of the output voltage is not pertinent, they appear to have considerable merit. Such methods usually involve the use of a motor as the amplifier load, working it against a counter-torque obtained from springs, weights or another motor. Problems common to these methods are motor shaft coupling and alignment, and the variation in motor torque with respect to the motor's electric poles and shaft position in a multipole motor. Additional problems encountered with the use of springs or weights are calibration and reading accuracy. These latter problems should not be serious when the counter-torque is obtained from another motor.

In applications wherein the phase angle of the output voltage is pertinent, however, the wattmeter method appears to offer definite advantages, especially with regard to the use of a dummy load which, as pointed out earlier in this paper, offers the flexibility of adjusting the load impedance to any desired value. This flexibility is of special value in applications such as the particular one discussed herein, due to the sensitivity of the magnitude and phase angle of the amplifier's output voltage to variations in load impedance.

Reactions of Bistable B-H Loops on Magnetic Amplifiers

R. E. MORGAN
MEMBER AIEE

MAGNETIC AMPLIFIERS commonly use 50% nickel-iron core materials with oriented crystals. These materials are commercially named Deltamax, Hypernic V, Orthonik, Orthonol, Permenorm, Permeron, etc. They are used successfully in many applications, but frequently when they are used underexcited in magnetic amplifiers (where the power supply voltage is insufficient to drive the core from negative to positive saturation), instability and slow response time occur.

The instability of magnetic amplifiers caused by 50% oriented nickel-iron cores has previously been described,[1] and the characteristics of these cores have been explained.[2-4] This paper presents measured **B-H** loops (kilogausses versus oersteds) with some characteristics of bistable minor **B-H** loops, and shows that instability (Fig. 1) and slow response time of magnetic amplifiers can be caused by the bistable **B-H** loops (Fig. 2). The use of a pulse to preset the core of the magnetic amplifier is described. The preset pulse forces the core to operate on a single minor **B-H** loop and causes the magnetic amplifier to have a stable characteristic (Fig. 3) and fast response (Fig. 4).

The term "bistable **B-H** loop" is used to indicate that a minor **B-H** loop of the core may remain stable at two flux position levels for the same external conditions (voltage and ampere-turns). Actually some cores have minor loops that are stable at more than two flux levels and that provide the conditions described in this paper, but for the purpose of simplicity, the **B-H** loops shown in this paper were obtained from cores that maintain these minor **B-H** loops in either of two flux position levels.

Paper 57-776, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted April 9, 1957; made available for printing May 5, 1958.

R. E. MORGAN is with the General Electric Company, Schenectady, N. Y.

Bistable B-H Loops

Bistable minor **B-H** loops are shown in Figs. 5 through 10 for a 50% nickel-iron core. These **B-H** loops show some characteristics that exist in bistable loops. Taken from a single core, they are not to be interpreted as typical or average. From 12 cores selected at random, 8 of the cores have **B-H** loops similar to those of Figs. 5 through 10, while the remaining 4 cores have symmetrical minor **B-H** loops (minor loops showed no signs of saturation). The a-c **B-H** loops (Figs. 5 through 8) were obtained by using a sine wave flux at 60 cps (cycles per second).

Bistable a-c minor **B-H** loops are shown in Fig. 5. The upper portion of the upper loop remains at the positive residual flux level ($+B_r$), and the lower portion of the lower loop remains at the negative residual flux level ($-B_r$). The upper loop occurs by applying $+25$ oersteds of direct current to the reactor, removing the direct current, and applying a sine wave flux at 60 cps to the reactor. The lower loop occurs in the same manner except that -25 oersteds are used. Figs. 6 through 8 show the a-c major **B-H** loop and several amplitudes of a-c minor **B-H** loops that cling to the positive residual flux density level $+B_r$.

Bistable d-c minor **B-H** loops are shown in Fig. 9. **B-H** loop A (dashes) and **B-H** loop B (dots) were obtained by cycling, very slowly, between $+0.13$ and -0.13 oersteds for many cycles. Loop A was started at $+B_r$ and loop B was started at $-B_r$. The bistable loops A and B are shown with the d-c major **B-H** loop (solid line) and two other minor loops that cling to $+B_r$.

The **B-H** characteristics (d-c) of Fig. 10 illustrate the "memory" nature of the core. The solid curve is the major d-c loop, the dash curve is a **B-H** characteristic originating from positive saturation, and the dotted curve originates from negative saturation. During the time that flux is moving away from the original saturation flux level, the characteristic follows close to the major **B-H** loop although the magnetomotive force H was removed ($H=0$ or even slightly reversed) and H reinstated. During the time that flux is moving toward the original saturation level, the **B-H** characteristic is farther inside the major d-c loop (dashed curve with H positive) than during the time that flux is moving away from the original saturation level. Fig. 10 shows that the core remembers the previous saturation polarity with magnetomotive force H at $H=0$ for various levels of flux density B.

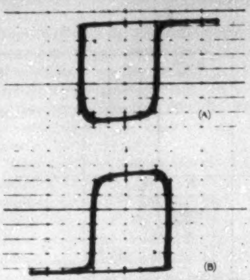

Fig. 5. Measured bistable minor B-H loops, 60 cps

Reaction of the Magnetic Amplifier

The bistable **B-H** loops react upon the magnetic amplifier by causing a double valued portion of the transfer characteristic (curve *A*, Fig. 3) and causing the output to respond slowly to the application of control current; see Fig. 4(C). These undesirable characteristics are corrected by a preset pulse as shown in curve *B* of Figs. 3 and 4(B). The doubled-value characteristic and the slow response can occur in any of the magnetic amplifier circuits[5] ("bridge," "center-tap," etc.), but the "half-wave" magnetic-amplifier circuit of Fig. 11 was chosen to present these characteristics because of the circuit's simplicity. The "half-wave" magnetic amplifier uses a pulse power supply instead of the usual sine wave supply.[5] The use of a pulse power supply for this circuit (Fig. 11) has previously been described.[6] The wave shape of the pulse power supply voltage is shown in Fig. 12(A) with a peak voltage $e_S = 100$ volts and a pulse width of 100 microseconds (approximately 2 degrees of a 60-cps wave). The preset pulse, Fig. 12(B), is compared to the supply pulse, Fig. 12(A), and the supply pulse voltage e_S is shown, Fig. 12(C), expanded in the time scale.

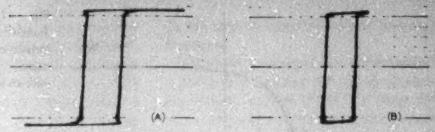

Fig. 7 (right). Measured minor B-H loops clinging to $+B_r$, 60 cps

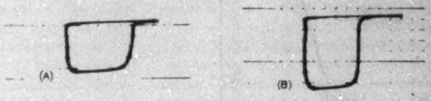

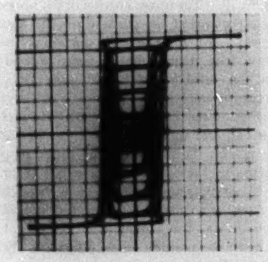

Fig. 8. Measured major and several minor B-H loops superimposed, 60 cps

CORRECTION OF THE DOUBLE-VALUED CONTROL CHARACTERISTIC

Curve *A* of Fig. 3 is the characteristic of the magnetic amplifier of Fig. 11 without bias ($I_B=0$) and without the preset pulse (S_2 open). The double-valued control characteristic (at $E_L<1.0$ volt) is caused by the bistable **B-H** loops as previously explained.[1] The application of the preset pulse (S_2 closed, Fig. 11) removes the double-valued characteristic as shown by curve *B* of Fig. 3. The preset pulse is applied (for 500 microseconds) shortly after the power pulse (Fig. 12) and drives the core (Fig. 11) positive to +30 oersteds, and transfers the core to the upper bistable **B-H** loop (Figs. 2 and 5). The preset pulse is applied for a longer interval and it provides more volt-seconds than the main power pulse in order to insure preset for all normal conditions of control, and the resistor (2,000 ohms, Fig. 11) limits the peak current of the preset pulse. The preset pulse forces the core into positive saturation after each power pulse. A winding, separate from the gate winding (power winding), is used for

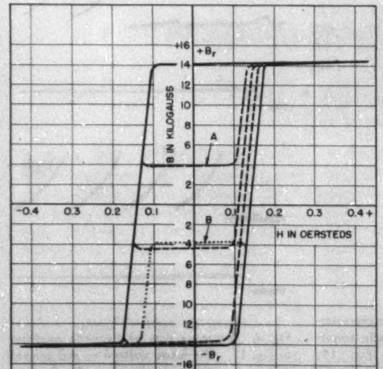

Fig. 9 (left). Measured major and minor B-H loops, d-c, including bistable minor loops A and B

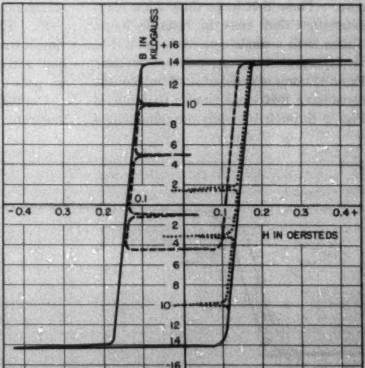

Fig. 10 (right). Measured major and minor B-H characteristics, d-c, showing memory property of the core

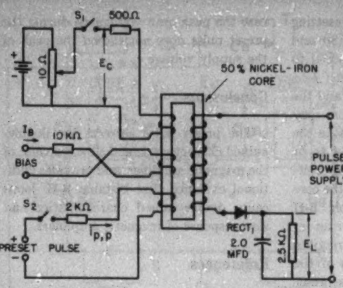

Fig. 11. Half-wave magnetic-amplifier circuit used to investigate the reaction of the bistable **B-H** loops

preset so that the preset current $i_{p,p}$ does not flow in the load circuit. While the core is saturated (+30 oersteds) by the preset pulse, the supply voltage $e_S=0$, Fig. 12(A) and the reaction of the preset pulse does not shift the characteristic of the magnetic amplifier very much nor does it change the gain.

The characteristic of the circuit and core without pulse preset and with a sine wave power supply (not shown) is approximately the same as that with the pulse power supply. The pulse preset principle can be used with a sine wave power supply (shown later) but the phasing of the preset pulse presents a problem. If the preset pulse lags the end of the conducting half-cycle of the power supply, there is insufficient time for resetting the core in most circuit applications and the minimum load voltage E_L is excessive. The pulse power supply provides ample time for reset between the end of the preset pulse and the following power pulse; see Fig. 12.

Correction of Slow Response

The reaction of the bistable **B-H** loops upon the magnetic amplifier causes slow response to control signals that drives the load voltage E_L from its minimum value to intermediate values (such as $E_L=3.0$ volts in Fig. 3). Response time up to 2 seconds has been observed with the circuit of Fig. 11 with a marginal control voltage of $E_C=-0.52$ volt. This condition being unusual and extreme is not shown in this paper. The response time shown in Fig. 4(A) is typical for the circuit of Fig. 11 with bias current $I_B=2.0$ milliamperes (equivalent of $E_C=-1.0$ volt in Fig. 3), switch S_2 open, and the application of control voltage $E_C=+0.55$ volt (providing net control of $E_C=-1.0+0.55=-0.45$ volt finally producing load voltage $E_L=3.0$ volts). The response time is slightly longer for the application of control voltage $E_C<0.55$ volt (producing $E_L<3.0$ volts).

The slow response time is caused by the time required to transfer from the lower bistable minor **B-H** loop (Figs. 2 and 5) to the upper minor **B-H** loop. This is corrected by the preset pulse. The preset pulse transfers the core from the lower minor to the upper minor **B-H** by the application of +30 oersteds by a method similar to that by which the minor loops of Fig. 5 are transferred. The same preset pulse that corrected the double-valued control characteristic corrects the slow response, as shown in Fig. 4(B). The preset amplitude of +30 oersteds is not critical, and the minimum amplitude depends upon the pulse length of the preset pulse and the particular core being applied.

Application of Preset Pulse to Magnetic Amplifiers Using Sine Wave Power Supply

The preset pulse, described in the foregoing, is applicable to magnetic amplifiers that use a sine wave power supply. A bridge type of magnetic amplifier is shown

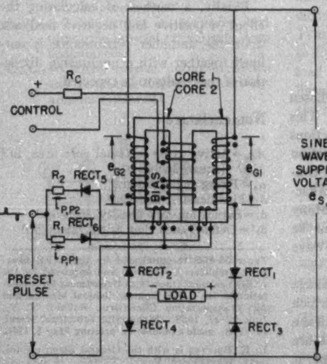

Fig. 13 (left). Full-wave bridge magnetic amplifier with preset pulse

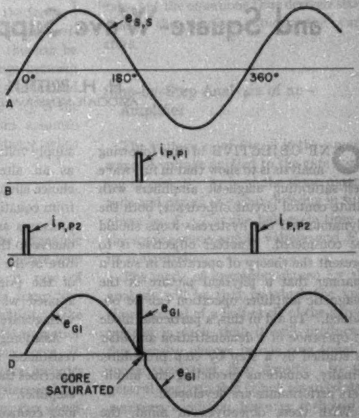

Fig. 14 (right). Phase relation and wave shapes of:

A—Supply voltage $e_{S,S}$
B—Preset pulse current $i_{P,P1}$
C—Preset pulse current $i_{P,P2}$
D—Gate voltage e_{G1} from circuit of Fig. 13

in Fig. 13, the circuit of which is typical to bridge circuits commonly used[5] in control circuits except that the preset pulse circuit is added. The preset pulse circuit consists of resistors R_1 and R_2, rectifiers rect_3 and rect_4, the associated windings of the reactor, and an a-c symmetrical pulse source. Fig. 14 shows the phase relations of the sine wave power supply, Fig. 14(A), preset pulse currents $i_{P,P1}$ and $i_{P,P2}$ Fig. 14(B) and (C), and gate winding voltage e_{G1}, Fig. 14(D).

Preset pulse current $I_{P,P1}$ is applied to core 1 in the same manner that the preset pulse is applied in the "half-wave" circuit of Fig. 11, and preset pulse current $i_{P,P2}$ is applied to core 2 likewise, except that current $i_{P,P2}$ is 180 degrees out of phase with current $i_{P,P1}$. The preset pulse is applied at the end of the conducting half-cycle of the corresponding gate circuit. Consider the reaction of the preset pulse current $i_{P,P1}$ upon core 1. Pulse current $i_{P,P1}$ is applied at 180 degrees of the supply voltage $e_{S,S}$ cycle, and pulse current $i_{P,P1}$ is applied for a sufficient time to saturate core 1 if core 1 is not already saturated at 180 degrees. Fig. 14(D) shows gate voltage e_{G1} when the circuit of Fig. 13 is producing minimum output ($e_{G1}=e_{S,S}$ during 0 degree to 180 degrees) and the core saturates during the preset pulse. In the case of a pure resistive load (Fig. 13), the core's maximum resetting volt-seconds ($\int e_{G1}\,dt$ between 180 and 360 degrees) are approximately equal to the maximum setting volt-second ($\int e_{G1}\,dt$ between zero and 180 degrees) and the preset pulse needs to force the core only the small amount necessary to make the setting volt-seconds at least equal to or slightly greater than the resetting volt-seconds. The preset pulse forces the core to operate on the positive bistable **B-H** loop. In the case of a resistive or an inductive load (commutated by rectifier rect_3 and rect_4), the volt-seconds of the gate winding ($+\int e_{G1}dt$) during the preset pulse need to be 5% or less of the volt-seconds of the gate winding between zero and 180 degrees. If the load in Fig. 13 had been a capacitive load, the possible resetting volt-seconds of the gate winding ($-\int e_{G1}dt$) between 180 and 360 degrees would be greater than the resetting volt-seconds for a resistive load and the pulse preset would have to force a greater flux change in the core for a capacitive load than a resistive load. Although in some applications, such as capacitive loads, the peak-induced gate voltage e_{G1} may be excessive during the preset pulse, most applications using resistance loads or inductive loads can obtain good results with a preset pulse length of about 5 degrees of the supply voltage $e_{S,S}$ cycle, in which case the peak gate voltage e_{G1} during the preset pulse does not exceed the peak of the supply voltage $e_{S,S}$.

Conclusions

The preset pulse corrects the double-valued characteristic and slow response of the magnetic amplifier, and provides additional evidence that bistable **B-H** loops cause double-valued characteristics and slow response of magnetic amplifiers.

Characteristics of Magnetic Amplifiers Utilizing Square-Loop Core Material and Square-Wave Supply Voltage

H. H. BRITTEN
ASSOCIATE MEMBER AIEE

ONE OBJECTIVE of the following analysis is to show that in full-wave self-saturating magnetic amplifiers with finite-control circuit impedance, both the dynamic and d-c hysteresis loops should be considered. Another objective is to present the theory of operation in such a manner that a physical picture of the magnetic amplifier operation can be obtained. To aid in this, a particular mode of operation of a demonstration amplifier is studied by a step by step procedure. Finally, equations predicting the amplifiers performance are developed.

With these objectives in mind, the supply voltage to the amplifier was chosen as an alternating square wave. This choice eliminated trigonometric functions from equations and simplified integration processes and, therefore, was more conducive to the formation of a physical picture of the amplifier's operation. Many of the principles thus derived can be applied where other than square-wave voltages are used.

Assuming infinite rectifier leakage resistance, a series is developed which describes the transient performance of the amplifier. For response times that are long compared to the half-cycle time, it will be shown how a time constant is derived from this series. Equations for power gain and dynamic power gain are derived in terms of amplifier constants.

The effect of finite rectifier leakage resistance is analyzed and equations expressing its influence on amplifier performance are developed.

Finally, a method of calculating the effect of positive and negative feedback upon the amplifier performance is outlined together with a qualitative discussion of the results to be expected.

Circuit

The magnetic amplifier circuit that will be used in this analysis is the center-tapped circuit of Fig. 1. This amplifier has two isolated cores, A and B. These cores have identical gate windings (between X_1 and X_2) and these are energized by the voltages e_A and e_B from transformer T. The resistance of the gate winding is normally R_G, however, if the forward characteristic of the rectifier is approximated by a linear resistance, this can be included in R_G. The windings between Y_1 and Y_2 on each core are interconnected to form the control winding. R_L is the load resistance and R_l is an assumed linear rectifier leakage resistance when the switches S are closed.

Assumptions

It is assumed that the dynamic hysteresis loop will exhibit square-loop characteristics for a constant rate of change of flux density. The term "dynamic hysteresis loop" is defined as the relationship between magnetic induction β and apparent magnetizing force H. The apparent magnetizing force includes that required by the d-c hysteresis loop, taken over the same operating flux densities, plus all magnetizing forces required to overcome eddy current effects associated with the rate of change of flux density. In this paper, it is assumed that the voltage e_A or e_B of Fig. 1, when applied directly to a gate winding of one core, will produce in that core the required rate of change of flux density to produce the dynamic hysteresis loop of Fig. 2. The d-c loop presumes a relatively low rate of change of flux density. In the following analysis, it will be assumed that during the portion of the cycle when the flux density of a core is changing due to the control voltage alone, the action will take place along the d-c loop. Another assumption regarding the curves of Fig. 2 is that they can only be traversed along constant H or β lines.

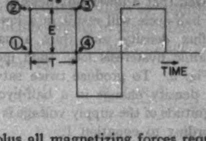

Fig. 3 (right). Square-wave voltage supply to gate of core B

There is assumed to be no leakage flux between the gate and control windings. The inductance of the gate winding during the saturation interval ($t_x<t<T$) is neglected. During the excitation interval ($0<t<t_x$) the voltage drop over the load and gate coil resistance, caused by the excitation current, is neglected.

The rectifiers are assumed to have a linear forward resistance (which is included in R_G) and an infinite leakage resistance until switches S are closed after which it is assumed to be the linear resistance R_l.

These approximations will produce second-order variations from observed data, but the equations thus derived show clearly the relations among the variables.

Step-by-Step Analysis of an Amplifier

The voltage e_B of Fig. 3 is the square-wave of voltage applied to the gate winding of core B. e_A is of the same magnitude and period as e_B but differing in time phase by T. T is the half-cycle time of the square-wave supply voltage and E is its magnitude.

The mode of operation chosen for the analysis will be that in which the volt-time integral of a half-cycle of the supply voltage is such that it will produce a flux density change in one core equal to twice saturation flux density. In the general analysis this is not assumed as a necessary condition, however, it should be realized that a lower flux density change per half-cycle will result in a lower rate of flux density and thus a narrower dynamic hysteresis loop than indicated in Fig. 2. To produce twice saturation flux density change in a half-cycle, the magnitude of the supply voltage is chosen according to equation 1.

$$E=\frac{1}{T}\int_0^T e_B dt=\frac{N_G A_{Fe}}{T}\int_{-\beta_s}^{+\beta_s} d\beta 10^{-8}$$
$$=\frac{2\beta_s A_{Fe} N_G 10^{-8}}{T} \quad (1)$$

The constants chosen for the demonstration amplifier are as follows:

$E=100$ volts
$H_{c,1}=0.25$ amp-turns/in.
$H_{c,2}=0.75$ amp-turns/in.
$\beta_s=100{,}000$ lines/in.^{2}
$A_{Fe}=0.625$ in.^{2}
$N_G=100$ turns
$N_c=100$ turns
$T=0.00125$ sec.
$l_{Fe}=8.0$ in.
$R_c=200$ ohms
$R_L=15$ ohms
$R_G=5$ ohms

The criterion that will be used to ascertain whether the amplifier is operating at a steady-state condition is as follows: If the conditions existing in both cores at the beginning of a half-cycle of supply voltage are exactly interchanged at the beginning of the next half-cycle, then the amplifier is in a steady-state operating mode. For the specific operating mode analyzed by the step-by-step method, wave shapes of load and control currents will be examined and the average values of these currents will be recorded.

The convention of polarities is as follows: When voltages are applied to a winding such that the polarity marked end is positive, the flux density change will be toward positive saturation. Similarly, when current flows into a winding at the polarity marked end, the resulting magnetic force will be positive.

On Figs. 2, 3, and 4 are marked specific points that will be referred to in following the amplifiers performance throughout a half-cycle of operation. For the specific operating mode to be examined, it will be assumed that $E_c=-8.0$ volts, and at the beginning of a positive half-cycle of voltage to the gate winding of core B (point 1, Fig. 3), conditions in core A are described by point 1, Fig. 2 ($\beta=+\beta_s$, $H=-H_{c,1}$) and core B by point 5, Fig. 2 ($\beta=0$, $H=-H_{c,1}$). As the voltage increases to point 2, Fig. 3, the current in the gate winding of core B and the load increases until the magnetic force of core B is at point 6, Fig. 2 ($\beta=0$, $H=+H_{c,2}$). At this time, the supply voltage appears across the gate winding of core B and $e_{G,B}=E$. Since the gate and control turns have been assumed equal $e_{c,B}=e_{G,B}=E$. The voltage across the control coil of core $B(e_{c,B})$ minus the control voltage E_c (in the normal range of the amplifier, the control voltage will be negative and thus will be additive with $e_{c,B}$) minus the drop across the control resistance appears across the control coil of core A. If the voltage drop across the control resistance is relatively small compared to $e_{c,B}$, the voltage across the control coil of core A will produce a rate of change of flux density in core A nearly equal to that in core B. Therefore, the flux density in core A is assumed to be changing along the dynamic hysteresis loop. Thus, the current in the control circuit increases until the magnetic force of core A is at $-H_{c,2}$ and is described by point 2, Fig. 2 ($\beta=+\beta_s$, $H=-H_{c,2}$). The control current ($i_{c,x}$) at this moment (point 1, Fig. 4(B)) is that required in the control coil to overcome the coercive force of the dynamic loop of core A. Its value is given by equation 2.

$$i_{c,x}=-\frac{l_{Fe}}{N_c}H_{c,2} \quad (2)$$

Using the constants for the demonstration amplifier, $i_{c,x}=-0.06$ amp. The load current ($i_{L,x}$) at this time (point 1, Fig. 4(A)) is that required in the gate coil of core B to overcome the coercive force of core B ($H_{c,2}$) plus the current reflected from the control coil of core B in overcoming the coercive force of core A. The excitation current at this point is given by equation 3. Again applying the given constants $i_{L,x}=0.120$ amp.

$$i_{L,x}=\frac{2H_{c,2}l_{Fe}}{N_G} \quad (3)$$

The load and control currents will remain constant at the foregoing values until core B saturates (point 7, Fig. 2). The time required for this to occur is called the excitation interval (t_x) and can be obtained by rearranging equation 1.

$$t_x=\frac{\beta_{B,x,F}A_{Fe}N_G}{E}(10^{-8}) \quad (4)$$

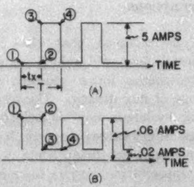

Fig. 4. Instantaneous control current

$\beta_{B,x,F}$ is defined as the flux density change represented between points 6 and 7 of Fig. 2. Using the constants of the demonstration amplifier, $t_x=0.000625$ sec. During the excitation interval, the flux density of core A is decreasing from positive saturation due to the voltage on its control winding which is the voltage from the control winding of core B minus the control voltage less the drop across the control resistance. This flux density change is defined as $\beta_{A,x,R}$ and is represented between points 2 and 3 of Fig. 2 and is determined by equation 5.

$$\beta_{A,x,R}=\frac{t_x e_{c,A}10^{-8}}{A_{Fe}N_c}=\frac{t_x 10^{-8}}{A_{Fe}N_c}\times$$
$$\left[E-E_c-\frac{H_{c,2}l_{Fe}R_c}{N_c}\right] \quad (5)$$

Applying the constants of the given amplifier, $\beta_{A,x,R}=96{,}000$ lines/in.^{2}. At the time core B is about to go into saturation, the load current is at point 2, Fig. 4(A); the control current is at point 2, Fig. 4(B); core B is at point 7, Fig. 2($\beta=+\beta_s, H=+H_{c,2}$); and core A is at point 3, Fig. 2 ($\beta=+4{,}000$, $H=-H_{c,2}$). Now core B saturates and its magnetic force is represented by point 8, Fig. 2. The load current ($i_{L,s}$) increases to a value given by equation 6 and is represented by point 3, Fig. 4(A). For the given amplifier $i_{L,s}=5.0$ amp.

$$i_{L,s}=\frac{E}{R_G+R_L} \quad (6)$$

Since there is no induction when core B is fully saturated, $e_{c,B}=0$. Now the only voltage in the control circuit is the relatively low control voltage, and the rate of change of flux density in core A decreases greatly. The assumption used in this analysis is that the coercive force of core A returns to the d-c hysteresis loop ($-H_{c,1}$) which is represented by point 4, Fig. 2. The control current at this time ($i_{c,s}$) is at point 3, Fig. 4(B), and is given by equation 7.

$$i_{c,s}=-\frac{l_{Fe}H_{c,1}}{N_c} \quad (7)$$

Using the given constants, $i_{c,s}=-0.02$ amp.

The load and control currents now remain at these values until the end of the saturation interval and are represented respectively at that time by point 4, Fig. 4(A) and point 4, Fig. 4(B). During the saturation interval ($T-t_x$), the control voltage causes a further decrease in flux density in core A. This is represented between points 4 and 5 of Fig. 2, which is defined as $\beta_{A,s,R}$ and is given by equation 8.

$$\beta_{A,s,R}=\frac{(T-t_x)e_{c,B}}{A_{Fe}N_c}10^8$$

$$=\frac{(T-t_x)10^8}{A_{Fe}N_c}\left[-E_c-\frac{H_{c,1}l_{Fe}R_c}{N_c}\right] \quad (8)$$

Again using the constants of the given amplifier in equation 8, $\beta_{A,s,R}=4{,}000$ lines/in.^{2}.

At the end of the half-cycle (point 4, Fig. 3), core B returns to point 1, Fig. 2 ($\beta=+\beta_s$, $H=-H_{c,1}$). Core A has returned from positive saturation flux density an amount equal to $\beta_{A,x,R}+\beta_{A,s,R}$ which in the given amplifier is 100,000 lines/in.^{2} and therefore core A is at point 5, Fig. 2 ($\beta=0$, $H=-H_{c,1}$). Thus, the conditions in the cores at the beginning of the positive half-cycle of e_A are exactly interchanged and thus fulfill the criterion for steady-state operation. The average control current I_c is given by equation 9.

$$I_c=\frac{1}{T}\int_0^{t_x} i_{c,x}dt+\frac{1}{T}\int_{t_x}^{T} i_{c,s}dt \quad (9)$$

If the excitation component of the load current is neglected, the average load current (I_L) is given by equation 10.

$$I_L=\frac{1}{T}\int_{t_x}^{T}\frac{E}{R_G+R_L}dt \quad (10)$$

Using the constants of the demonstration amplifier, the average control and load current for the mode investigated were respectively −0.04 and 2.5 amp.

The theoretical $\beta-H$ loop followed by a core in a full-cycle of operation, and for the given conditions, is outlined by the numbers 1 through 8 in Fig. 2.

General Analysis

The maximum voltage that can be applied to a magnetic amplifier and still maintain full control is given by equation 1. However, it may be desirable in some cases to design an underexcited magnetic amplifier in which the maximum flux density swing in a core is not $2\beta_s$ at the design voltage. Define a flux density β_s' such that $\beta_s'<\beta_s$. Also define a quantity as in equation 11.

$$f=\frac{1}{2T} \quad (11)$$

Now, eliminating T from equation 1 by means of equation 11 and replacing β by β_s', equation 12 is obtained which defines the supply voltage of the amplifier.

$$E=4fN_GA_{Fe}\beta_s'\times10^{-8} \quad (12)$$

Assume the amplifier is operating at a general steady-state operating point and time is such that a positive half cycle of voltage to the gate winding of core B is just beginning (point 1, Fig. 3). At this time, core A will be at point 1, Fig. 2 ($\beta=+\beta_s$, $H=-H_{c,1}$) and core B will be at some general level of flux density at a coercive force of $-H_{c,1}$. As the voltage e_B rises to E (point 2, Fig. 3) and neglecting the voltage drop over the gate and load resistance by the excitation current, the gate voltage of core B is $e_{G,B,x}=E$. The voltage across the control coil of core B at this time is given by equation 13.

$$e_{c,B,x}=\frac{N_c}{N_G}e_{G,B,x}=\frac{N_c}{N_G}E \quad (13)$$

The control voltage $e_{c,B,x}$, minus the control voltage E_c less the drop over the control resistance drives core A to a coercive force of $-H_{c,2}$ and a control current flows equal to:

$$i_{c,x}=-\frac{H_{c,2}l_{Fe}}{N_c} \quad (14)$$

The current in the gate winding of core B and load at this time is that required through the gate turns to overcome the coercive force of core B plus the reflected control current. This is given in equation 15.

$$i_{G,B,x}=i_{L,x}=\frac{H_{c,2}l_{Fe}}{N_G}-\frac{N_c}{N_G}i_{c,x}=\frac{2H_{c,2}l_{Fe}}{N_G} \quad (15)$$

Now as time progresses, the flux density of core B will increase toward positive saturation. If the flux density change required to produce saturation is defined as $\beta_{B,x,F}$, the time for saturation to occur or the excitation interval (t_x) is given by equation 16.

$$t_x=\frac{N_GA_{Fe}\beta_{B,x,F}}{E}10^{-8} \quad (16)$$

The flux density change of core A from positive saturation during the excitation interval is defined as $\beta_{A,x,R}$. This flux density change is due to the voltage impressed upon the control coil of core A and is given by equation 17.

$$\beta_{A,x,R}=\frac{10^8}{N_cA_{Fe}}\left[\frac{N_c}{N_G}E-E_c-\frac{H_{c,2}l_{Fe}R_c}{N_c}\right]t_x \quad (17)$$

After core B saturates, the load current increases to a value limited by the load and gate resistance. The induced voltage from the control coil of core B becomes zero and the voltage in the control circuit reduces to the control voltage (E_c). It is assumed that the control voltage is small enough that core A returns to the coercive force of the d-c hysteresis loop ($-H_{c,1}$). During the saturation interval the control voltage causes an additional change of flux density in core A from positive saturation defined as $\beta_{A,s,R}$ and given by equation 18.

$$\beta_{A,s,R}=\frac{10^8}{N_cA_{Fe}}\left[-E_c-\frac{H_{c,1}l_{Fe}R_c}{N_c}\right](T-t_x) \quad (18)$$

The criterion for steady-state operation as stated previously is given by

$$\beta_{B,x,F}=\beta_{A,x,F}+\beta_{A,s,R} \quad (19)$$

Substituting from equations 16, 17, and 18 into 19, the following relation is obtained:

$$E_c=-\frac{l_{Fe}R_c(H_{c,2}-H_{c,1})}{N_c}\frac{t_x}{T}-\frac{l_{Fe}R_cH_{c,1}}{N_c} \quad (20)$$

where

$$-\frac{l_{Fe}R_cH_{c,2}}{N_c}\lesseqgtr E_c\lesseqgtr\frac{l_{Fe}R_cH_{c,1}}{N_c}$$

The average load current as a function of the duration of the excitation interval is given by equation 21.

$$I_L=\frac{1}{T}\int_0^{t_x} i_{L,x}dt+\frac{1}{T}\int_{t_x}^{T}\frac{E}{R_G+R_L}dt \quad (21)$$

Substituting for $i_{L,x}$ from equation 15 into 21 and integrating:

$$I_L=\frac{2H_{c,2}l_{Fe}}{N_G}\frac{t_x}{T}+\frac{E}{R_L+R_G}\left(\frac{T-t_x}{T}\right) \quad (22)$$

where

$$0\lesseqgtr t_x\lesseqgtr T$$

By combining equations 20 and 22, the steady-state control characteristic of average load current versus control voltage can be obtained as in equation 23.

$$I_L=\frac{2H_{c,2}}{N_G(H_{c,2}-H_{c,1})}\left[-l_{Fe}H_{c,1}-\frac{E_cN_c}{R_c}\right]+\frac{E}{(R_L+R_G)l_{Fe}(H_{c,2}-H_{c,1})}\left[l_{Fe}H_{c,2}+\frac{E_cN_c}{R_c}\right] \quad (23)$$

where

$$-\frac{H_{c,2}l_{Fe}R_c}{N_c}\lesseqgtr E_c\lesseqgtr-\frac{H_{c,1}l_{Fe}R_c}{N_c}$$

Since the characteristics of magnetic amplifiers are in general plotted in terms of load and control current, the control voltage in equation 23 may be replaced by control current as follows:

$$I_L=\frac{2H_{c,2}}{N_G(H_{c,2}-H_{c,1})}[-l_{Fe}H_{c,1}-N_cI_c]+\frac{E}{(R_L+R_G)l_{Fe}(H_{c,2}-H_{c,1})}\times[l_{Fe}H_{c,2}+N_cI_c] \quad (24)$$

where

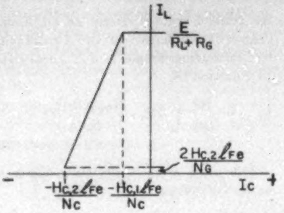

Fig. 5. Steady-state transfer function of amplifier

$$-\frac{H_{c,2}l_{Fe}}{N_c} \gtreqless I_c \gtreqless -\frac{H_{c,1}l_{Fe}}{N_c}$$

From equation 24 the steady-state amplifier characteristic may be plotted as in Fig. 5.

Equation 24 may be greatly simplified if the excitation component of load current is neglected. The effect of this is to drop the lower end of the characteristic, shown in Fig. 5, to zero. Using this simplification, equation 24 reduces as in 25.

$$I_L = \frac{E}{R_L+R_G}\left[\frac{H_{c,2}}{H_{c,2}-H_{c,1}} + \frac{N_c I_c}{l_{Fe}(H_{c,2}-H_{c,1})}\right] \tag{25}$$

where

$$-\frac{H_{c,2}l_{Fe}}{N_c} \gtreqless I_c \gtreqless \frac{H_{c,1}l_{Fe}}{N_c}$$

TRANSIENT RESPONSE ASSUMING NO RECTIFIER LEAKAGE

When the magnetic amplifier is operating steady-state, the control voltage must be such that the flux density change of the core going into positive saturation is equal to the total reset flux density change of the other core (equation 19). When this condition is transiently upset by a change in control voltage, the amplifier will seek a new period of excitation interval such that this condition will again prevail. The time for this to occur is of vital interest to the designers of magnetic amplifiers.

In studying the response of the amplifier, the cores need no longer be referred to as *A* and *B*. It is evident at this point that in any half-cycle, one core is going into positive saturation while the other is being reset from positive saturation. The core going into positive saturation determines the excitation interval of that half-cycle according to equation 16. If the flux density change required before saturation occurs is defined as β_F, then equation 16 can be expressed as in 26.

$$t_x = \frac{N_G A_{Fe} 10^{-8}}{E}\beta_F \tag{26}$$

The reset flux density change from positive saturation is defined as β_R and is obtained by adding equations 17 and 18 as follows:

$$\beta_R = \frac{10^8}{N_c A_{Fe}}\left[\frac{N_c}{N_G}E + \frac{l_{Fe}R_c}{N_c}(H_{c,1}-H_{c,2})\right]t_x + \frac{10^8}{N_c A_{Fe}}\left[-E_c - \frac{H_{c,1}l_{Fe}R_c}{N_c}\right]T \tag{27}$$

Now define

$$K_1 = \frac{N_G A_{Fe} 10^{-8}}{E} \tag{28}$$

$$K_2 = \frac{10^8}{N_c A_{Fe}}\left[\frac{N_c}{N_G}E + \frac{l_{Fe}}{N_c}(H_{c,1}-H_{c,2})\right] \tag{29}$$

$$K_c = \frac{10^8}{N_c A_{Fe}}\left[-E_c - \frac{H_{c,1}l_{Fe}R_c}{N_c}\right]T \tag{30}$$

K_c will be referred to as the control constant which may take on different values as a function of the control voltage E_c. Substituting from equations 28, 29, and 30 into 26 and 27 gives the following

$$t_x = K_1\beta_F \tag{31}$$

$$\beta_R = K_2 t_x + K_c \tag{32}$$

The criterion for steady-state operation is that $\beta_F = \beta_R$. If the steady-state excitation interval is defined as $t_{x,ss}$, equation 33 can be obtained from equations 31 and 32.

$$t_{x,ss} = \frac{K_1 K_c}{1-K_1K_2} \tag{33}$$

It is clear that the reset flux density of a core in one half-cycle becomes the forward flux density and determines the excitation interval in the following half-cycle. Keeping this in mind and by the use of equations 31 and 32, the transient response of the magnetic amplifier can be obtained.

Refer to Fig. 6 and assume that prior to the half-cycle represented by the shaded half-cycle the amplifier was at a steady-state condition determined by its control constant being at some specific value $K_c = K_{c1}$. The corresponding steady-state excitation is $t_{x,ss} = t_{x,ss1}$. From equation 33:

$$t_{x,ss1} = \frac{K_1 K_{c1}}{1-K_1K_2} \tag{34}$$

At the beginning of the shaded half-cycle, assume the control constant is changed by means of the control voltage to a new value $K_c = K_{c,2}$ and the response of the amplifier is desired in the following half-cycles: 1, 2, 3, ...*n*.

In the first half-cycle after the shaded one, the excitation time will be determined by the core going into positive saturation according to equation 31. Thus:

$$t_{x,1} = K_1\beta_{F1} \tag{35}$$

However, the forward flux density in the first half-cycle was the reset flux density of the shaded half-cycle which was from equation 32:

$$\beta_{R0} = K_2 t_{x,ss1} + K_{c,2} \tag{36}$$

Since $\beta_{F1} = \beta_{F0}$, using 35 and 36 gives:

$$t_{x,1} = K_1[K_2 t_{x,ss1} + K_{c,2}] \tag{37}$$

The reset flux density in the first half-cycle according to equation 32 is given by equation 38.

$$\beta_{R1} = K_2 t_{x,1} + K_{c,2} \tag{38}$$

Combining equations 37 and 38 gives:

$$\beta_{R1} = (K_1K_2^2)t_{x,ss1} + K_1K_2K_{c,2} + K_{c,2} \tag{39}$$

In the second half-cycle, the excitation interval $t_{x,2}$ is:

$$t_{x,2} = K_1\beta_{F2} = K_1\beta_{R1} \tag{40}$$

Substituting for β_{R1} from equation 39 gives:

$$t_{x,2} = (K_1K_2)^2 t_{x,ss1} + K_1^2K_2K_{c,2} + K_1K_{c,2} \tag{41}$$

This process may be continued to the *n*th half-cycle and the excitation interval for this half-cycle may be expressed as:

$$t_{x,n} = (K_1K_2)^n t_{x,ss1} + \frac{K_{c,2}}{K_2}[K_1K_2 + (K_1K_2)^2 + \ldots + (K_1K_2)^n] \tag{42}$$

Equation 42 may be rewritten as follows:

$$t_{x,n} = (K_1K_2)^n t_{x,ss1} + K_1K_{c,2}[1 + K_1K_2 + (K_1K_2)^2 + \ldots + (K_1K_2)^{n-1}] \tag{43}$$

Summing the geometric series of equation 43, it may be expressed as follows:

$$t_{x,n} = (K_1K_2)^n t_{x,ss1} + \frac{K_1K_{c,2}}{1-K_1K_2}[1-(K_1K_2)^n] \tag{44}$$

Now by the use of equation 33, the ultimate steady-state excitation interval $t_{x,ss2}$ may be expressed as in equation 45.

$$t_{x,ss2} = \frac{K_1K_{c,2}}{1-K_1K_2} \tag{45}$$

Substituting from equation 45 into 44 gives:

$$t_{x,n} = (t_{x,ss1} - t_{x,ss2})(K_1K_2)^n + t_{x,ss2} \tag{46}$$

By use of equation 46, the response of the magnetic amplifier can be determined

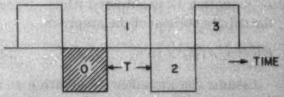

Fig. 6. Square-wave supply voltage

regardless of its speed of response. Such an expression is useful where response times approach the half-cycle time.

If the response time of the amplifier is relatively long compared to a half-cycle a time constant may be derived. The following equivalency may be written as follows:

$$(K_1K_2)^n = \epsilon^{n \log_e K_1K_2} \tag{47}$$

Equations 46 and 47 can be combined as in 48:

$$t_{x,n} = (t_{x,s.1} - t_{x,ss2})\epsilon^{n \log_e K_1K_2} + t_{x,ss2} \tag{48}$$

Since the response time is assumed to be long compared to half-cycle time, time as a function of the nth half-cycle and half-cycle time is approximately:

$$t \cong nT \tag{49}$$

Combining equations 48 and 49:

$$t_x = (t_{x,ss1} - t_{x,ss2})\epsilon^{-\left(\frac{\log_e K_1K_2}{T}\right)t} + t_{x,ss2} \tag{50}$$

It is evident from equation 50 that the response of the amplifier is exponential. The fact that $K_1K_2<1$ will be apparent later. Thus, the term $\log_e K_1K_2<0$ and since time constants are normally expressed as positive numbers, the negative exponent was introduced in equation 50. Define the term "time constant" (T_c) as follows:

$$T_c = -\frac{T}{\log_e K_1K_2} \tag{51}$$

Using equations 28 and 29, K_1K_2 can be expressed as follows:

$$K_1K_2 = 1 - \frac{N_G l_{Fe} R_c}{N_c^2 E}(H_{c,2} - H_{c,1}) \tag{52}$$

Eliminate E from equation 52 by means of equation 12 and define a quantity x as in equation 53.

$$K_1K_2 = 1 - \frac{l_{Fe} R_c 10^8}{4fN_c^2 A_{Fe} \beta_s'}(H_{c,2} - H_{c,1}) = 1 - x \tag{53}$$

Now eliminate K_1K_2 from equation 51 by means of the quantity defined in equation 53.

$$T_c = -\frac{T}{\log_e (1-x)} \tag{54}$$

Restricted to $0 \gtreqless x << 1$

It is obvious from equation 54 that $0 \gtreqless x \gtreqless 1$ covers a range of time constants from half-cycle time T to infinity. A previous assumption presumed investigating only response times that were relatively long compared to half-cycle time, therefore the range of x is restricted to $0 \gtreqless x << 1$.

Following is the infinite series expression for $\log_e(1-x)$.

$$\log_e(1-x) = -x - \frac{x^2}{2} - \frac{x^3}{3} - \ldots\ldots \tag{55}$$

An approximation for equation 55 when $x<<1$ is given in equation 56.

$$\log_e(1-x) \cong -x \tag{56}$$

when $x<<1$

Now substitute for $\log_e(1-x)$ from equation 56 into 54 and replace x by the value defined in equation 53.

$$T_c = \frac{2N_c^2 A_{Fe} \beta_s' 10^{-8}}{l_{Fe} R_c (H_{c,2} - H_{c,1})} \tag{57}$$

POWER GAIN (INFINITE RECTIFIER LEAKAGE RESISTANCE)

Power gain P_G is a useful measure of amplifier performance and is defined as follows:

$$P_G = \left(\frac{dI_L}{dI_c}\right)^2 \frac{R_L}{R_c} \tag{58}$$

Using equations 12, 25, and 58, the following expression for power gain can be obtained:

$$P_G = \frac{16f^2 N_G^2 N_c^2 A_{Fe}^2 \beta_s'^2 10^{-16}}{\frac{R_c}{R_L}(R_L + R_G)^2 l_{Fe}^2 (H_{c,2} - H_{c,1})^2} \tag{59}$$

DYNAMIC POWER GAIN (INFINITE RECTIFIER LEAKAGE RESISTANCE)

Dynamic power gain is defined as:

$$P_D = \frac{\left(\frac{dI_L}{dI_c}\right)^2 \frac{R_L}{R_c}}{T_c} = \frac{P_G}{T_c} \tag{60}$$

Substituting from equation 57 and 59 into 60:

$$P_D = \frac{8f^2 N_G^2 R_L A_{Fe} \beta_s' 10^{-8}}{(R_L + R_G)^2 l_{Fe} (H_{c,2} - H_{c,1})} \tag{61}$$

USE OF EQUATIONS

Previously, constants were assigned to a demonstration amplifier. If these constants are applied to equations 25, 57, 59 and 61, the results are as follows:

$I_L = 5[1.5 + 25I_c]$

where $-0.06 \gtreqless I_c \gtreqless -0.02$

$T_c = 0.0156$ sec.
$P_G = 1170$
$P_D = 75{,}000$

STEADY-STATE CHARACTERISTICS ASSUMING RECTIFIER LEAKAGE

The switches of Fig. 1 are now closed thus simulating rectifier leakage R_l. The excitation interval is still described by equation 16. If it is assumed that the voltage drop across the control resistance is small compared to induced voltages in the control winding, then $e_{c,B} \cong e_{c,A}$ and $e_{G,B} \cong e_{G,A}$ If this is true, the voltages $e_{G,A} \cong e_A$ and $e_{G,B} \cong e_B$ and the leakage resistance will have little influence on the reset flux density during the excitation interval and equation 17 still describes the reset flux density change during this interval. During the saturation interval, the leakage resistance will have a pronounced influence on the reset flux density. If gate and forward rectifier resistance are assumed negligible compared to load resistance, it can be shown that the reset flux density change in this interval is described by equation 62.

$$\beta_{A,S,R} = \frac{10^8}{N_c A_{Fe}\left[1 + \left(\frac{N_G}{N_c}\right)^2 \frac{R_c}{R_l}\right]} \times \left[-E_c - \frac{H_{c,1} l_{Fe} R_c}{N_c} + \frac{2EN_G R_c}{N_c R_l}\right](T - t_x) \tag{62}$$

To simplify the analysis, it will be assumed that:

$$1 >> \left(\frac{N_G}{N_c}\right)^2 \frac{R_c}{R_l}$$

This assumption implies that the leakage current is derived from a constant current source or that the leakage resistance is very large compared to the reflected control resistance. This condition normally exists except where deliberate leakage is introduced as a negative feedback. With this assumption, equation 62 reduces to:

$$\beta_{A,S,R} = \frac{10^8}{N_c A_{Fe}}\left[-E_c - \frac{H_{c,1} l_{Fe} R_c}{N_c} + \frac{2EN_G R_c}{N_c R_l}\right](T - t_x) \tag{63}$$

The conditions that must exist for steady-state operation are still described by equation 19. Substituting into equation 19 from equations 16, 17, and 63 results in equation 64.

$$I_c = -\frac{t_x}{T}\frac{l_{Fe}}{N_c}\left[H_{c,2} - H_{c,1} + \frac{2EN_G}{R_l l_{Fe}}\right] - \frac{l_{Fe}}{N_c}\left[H_{c,1} - \frac{2EN_G}{l_{Fe} R_l}\right] \tag{64}$$

Using equation 22 and 64 and neglecting the excitation component of load current, the following expression for load current can be obtained as in equation 65

$$I_L = \frac{E}{R_L + R_G}\left[\frac{H_{c,2}}{H_{c,2} - H_{c,1} + \frac{2EN_G}{R_l l_{Fe}}} + \frac{N_c I_c}{l_{Fe}\left[H_{c,2} - H_{c,1} + \frac{2EN_G}{R_l l_{Fe}}\right]}\right] \tag{65}$$

where

$$-\frac{l_{Fe} H_{c,2}}{N_c} \gtreqless I_c \gtreqless -\frac{l_{Fe}}{N_c}\left(H_{c,1} - \frac{2EN_G}{l_{Fe} R_l}\right)$$

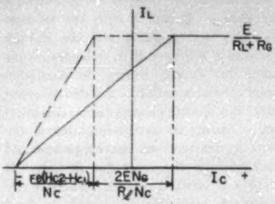

Fig. 7. Steady-state transfer function with rectifier leakage

Load current as a function of control current is plotted in Fig. 7. The dashed curve indicates the characteristic with infinite rectifier leakage resistance.

Transient Response with Rectifier Leakage

The transient response may be analyzed in exactly the same manner as outlined previously. Equation 28 is unchanged and 29 and 30 becomes respectively:

$$K_2=\frac{10^8}{N_cA_{Fe}}\left[\frac{N_c}{N_G}E+\frac{l_{Fe}R_c}{N_c}(H_{c,1}-H_{c,2})-\frac{2EN_GR_c}{N_cR_l}\right] \quad (66)$$

$$K_c=\frac{10^8}{N_cA_{Fe}}\left[-E_c-\frac{H_{c,1}l_{Fe}R_c}{N_c}+\frac{2EN_GR_c}{N_cR_l}\right] \quad (67)$$

Following the procedure established previously, it can be ascertained that the time constant including rectifier leakage ($T_{c,l}$) is expressed by equation 68.

$$T_{c,l}=\frac{T}{\frac{l_{Fe}R_c10^8}{4fN_c^2A_{Fe}\beta_s'}(H_{c,2}-H_{c,1})+\frac{2N_G^2R_c}{N_c^2R_l}} \quad (68)$$

The expression for time constant without rectifier leakage (T_c), given by equation 57, can be substituted in equation 68 which can then be rewritten as follows:

$$T_{c,l}=\frac{T_c}{1+\frac{4fN_G^2R_c}{N_c^2R_l}T_c'} \quad (69)$$

Investigation discloses that rectifier leakage is a type of negative feedback. Further analysis will show that decreasing rectifier leakage resistance will reduce the dynamic power gain, thus resulting in a longer time constant for a given power gain in a specific amplifier. In general, speed of response may be traded for stability of the transfer characteristic by means of negative feedback. However, when the negative feedback is introduced by means of rectifier leakage, the feedback function will be variable if leakage is a function of temperature. Thus, the over-all effect of rectifier leakage is detrimental.

Qualitative Discussion of Positive and Negative Feedback

Effects of positive and negative feedback may be analyzed by the method outlined previously. If a negative feedback is derived by passing the load current of the amplifier through a small control winding, it can generally be assumed that the feedback is from a constant current source to the extent that transient voltages induced into the load circuit through the feedback winding may be neglected. Since the feedback is only active during the saturation interval, only the reset flux density equation during the saturation interval is altered. Equation 62 can be rewritten to include the effect of positive and negative current feedback as follows:

$$\beta_{A,S,R}=\frac{10^8}{N_cA_{Fe}}\left[-E_c-\frac{H_{c,1}l_{Fe}R_c}{N_c}+\frac{2EN_GR_c}{N_cR_l}\pm\frac{EN_fR_c}{N_c(R_L+R_G)}\right](T-t_x) \quad (70)$$

Here the positive and negative signs are associated with negative and positive feedback respectively.

Again the procedures for obtaining response, power gain, etc. are as outlined previously. With negative feedback, it will be found that the dynamic power gain is lowered. The loss in speed of response, however, has been traded for stability of the transfer characteristic. With positive feedback, the converse is true.

Steady-State Transfer Characteristic with Sinusoid Supply

If the assumption is made that during the excitation interval a core is being reset along the dynamic hysteresis loop and during the saturation interval it is being reset along the d-c loop, equation 20 is valid for a sine wave of supply voltage to the gate windings. Equation 20 may be rewritten in terms of control current and a "firing" angle α_x as follows:

$$I_c=-\frac{l_{Fe}(H_{c,2}-H_{c,1})}{N_c}\frac{\alpha_x}{\pi}-\frac{H_{c,1}l_{Fe}}{N_c} \quad (71)$$

where $0\lesseqgtr\alpha_x\lesseqgtr\pi$. The average load current as a function of firing angle is given by equation 72:

$$I_L=\frac{1}{T}\left(\frac{E_m}{R_L+R_G}\right)\int_{\alpha x/\omega}^{\pi/\omega}\sin\omega t\,dt \quad (72)$$

Performing the indicated integration:

$$I_L=\frac{E_m}{\pi(R_L+R_G)}[1+\cos\alpha_x] \quad (73)$$

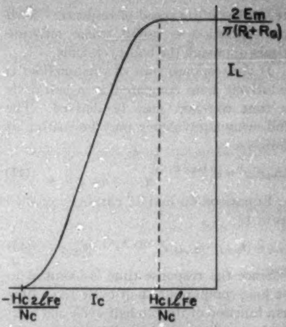

Fig. 8. Theoretical transfer characteristic with sinusoidal supply voltage

Average load current as a function of average control current may be obtained by eliminating α_x from equations 71 and 73 as follows:

$$I_L=-\frac{E_m}{\pi(R_L+R_G)}\left[1+\cos\frac{-N_c\pi}{l_{Fe}(H_{c,2}-H_{c,1})}\times\left(I_c+\frac{H_{c,1}l_{Fe}}{N_c}\right)\right] \quad (74)$$

The theoretical steady-state transfer function of a magnetic amplifier with sinusoidal supply voltage is shown in Fig. 8.

Test Results

A toroidal amplifier using Orthonol cores was constructed and tested in the circuit of Fig. 1 and with a square-wave supply voltage. The constants of the amplifier were as follows:

$N_G=535$ turns
$N_c=600$ turns

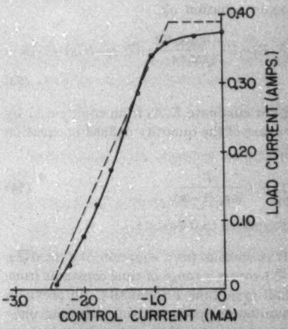

Fig. 9. Test amplifier transfer characteristic with square wave supply voltage

——Actual
– – –Theoretical

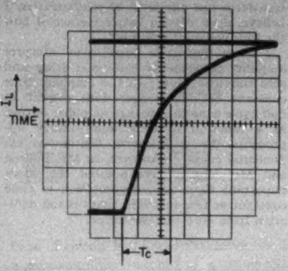

Fig. 10 (left). Response time of test amplifier (sweep time 20 milliseconds/centimeter)

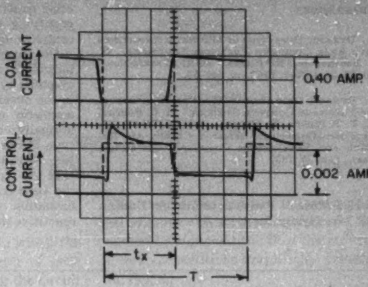

Fig. 11 (right). Load and control current of test amplifier

$E=40$ volts
$T=1/800$ sec.
$H_{c,1}=0.114$ AT/in.
$H_{c,2}=0.342$ AT/in.
$l_{Fe}=3.94$ in.
$A_{Fe}=0.084$ in.^{2}
$R_G=3$ ohms
$R_L=100$ ohms
$R_c=1000$ ohms

Using the foregoing constants, the transfer characteristic of the amplifier according to equation 25 is:

$$I_L=0.388[1.5+666I_c]$$

where $-0.0025 \gtreqless I_c \gtreqless -0.00075$

The theoretical amplifier characteristic is plotted as a dashed line on Fig. 9 and the actual test data are the solid line curve.

The amplifier time constant calculated by means of equation 57 is as follows:

$$T_c=\frac{2(600)^2(0.084)(55{,}500)10^{-8}}{3.94(1{,}000)(0.342-0.114)}=0.037 \text{ sec}$$

Fig. 10 shows the actual response of the amplifier as a function of time on a cathode-ray oscillograph and recorded by a Land camera. The sweep calibration on the cathode-ray oscillograph was 20 milliseconds per centimeter. The measured time constant was 0.039 sec which is in close agreement with the calculated value.

Using the constants of the test amplifier, the instantaneous load and control currents during the excitation and saturation interval may be calculated as follows:

$$i_{c,s}=-\frac{l_{Fe}H_{c,1}}{N_c}=-\frac{3.94(0.114)}{600}$$
$$=-0.00075 \text{ amp}$$

$$i_{c,x}=-\frac{l_{Fe}H_{c,2}}{N_c}=-\frac{3.94(0.342)}{600}$$
$$=-0.00225 \text{ amp}$$

$$i_{L,s}=\frac{E}{R_L+R_G}=\frac{40}{103}=0.388 \text{ amp}$$

Fig. 11 shows the actual instantaneous load and control currents during the excitation and saturation interval. The dashed lines in Fig. 11 show the theoretical values of these currents to be in close agreement with actual values.

Conclusion

A method of calculating the performance of an amplifier utilizing square-loop core material an alternating square-wave voltage supply has been shown to be in close agreement with observed data. It is felt that the elimination of trigonometric functions allows a clearer physical picture of how the amplifier operates. The theoretical steady-state transfer function was extended to the case of a sinusoidal supply voltage. The time constant derived for the square wave of supply voltage indicates that the time constant is proportional to the supply voltage. It is felt that if this analysis were extended to the general supply voltage, the time constant at any point on the transfer function might be found to be proportional to the slope of the transfer function.

Discussion

H. C. Bourne, Jr., and D. Nitzan (University of California, Berkeley, Calif.): The discussers note that the author has used the same model for the rectangular core material and consequently obtains the identical results for the center-tap circuit with no rectifier leakage as obtained in a previous paper[1] for the alternating-output circuit. Rectifier leakage, when described in terms of a reverse rectifier resistance, produces slightly different results for the three basic self-saturating circuits because of the different reverse voltages involved. In a less available publication[2] a general analysis of all three circuits with square-wave supply voltage and rectifier leakage is in complete agreement with the author's results.

The author uses a repetitive technique to obtain an expression for the excitation time in the *n*th half-cycle, reduces the series form to a closed form, and obtains an expression for the time constant. It might be pointed out that the implied difference equation

$$t_{x,n+1}=K_1B_{F,n+1} \tag{31A}$$

$$B_{R,n}=K_2t_{x,n}+K_{c,n} \tag{32A}$$

$B_{R,n}=B_{F,n+1}$ (from statement following equation 33)

$$t_{x,n+1}=K_1K_2t_{x,n}+K_1K_{c,n}$$

may be transformed directly using Laplace or *z*-transform techniques to obtain the same result in the form of a dynamic transfer function. Possibly the advantage of the series form lies in the clear physical picture which it gives of the discrete nature of the magnetic amplifier operation in the real time domain. However, from a systems viewpoint, the ultimate goal is a dynamic transfer function, which can be constructed from the author's results, of course.

The discussers believe that the author has been too severe, at least from a mathematical viewpoint, in the restrictions placed on the expressions for time constant in equations 50 and 54. Certainly, when using the term "time constant" in dealing with discrete systems some care in interpretation is necessary, but it seems perfectly logical to interpret $K_1K_2=0$, $x=1$, $T_c=0$ as an exponential response with zero time constant. Since in the author's definition, time did not start until a half-cycle after the application of the change in control voltage, the familiar half-cycle delay has been correctly implied. The actual restrictions on the validity of these expressions for fast response times concern the validity of the core representation and the possibility of gate rectifier unblocking under these conditions.

H. H. Britten: I wish to thank Mr. Bourne and Mr. Nitzan for their references to two other papers of similar content. It is indeed gratifying that independent works are in complete agreement.

One purpose of this paper was to help formulate a physical picture of magnetic amplifier type of operation. This is needed in the development of new circuits that use magnetic amplifiers outside of what is normally considered magnetic amplifier type of operation. Thus, Mr. Bourne and Mr. Nitzan are correct in their assumption that the repetitive technique, for obtaining the time constant, was used to aid in the formation of the physical picture. The repetitive method is not as concise as the *z*-transform but the level of mathematics, I believe, does allow a better picture of how the time constant is formed.

I agree that it is possible to interpret amplifier response as half-cycle delay and zero time constant. As the amplifier time constant becomes longer with respect to half-cycle time the average amplifier output as a function of time more nearly approaches the well known continuous exponential curve. However, as Mr. Bourne and Mr. Nitzan have pointed out, more important than the interpretation of time constant at fast response times is the deviation from core representation.

Triggering in the Reversible Half-Wave Magnetic Amplifier

D. L. MCMURTRIE
MEMBER AIEE

J. P. WARD
ASSOCIATE MEMBER AIEE

THIS PAPER describes a type of instability or triggering observed in the half-wave bridge circuit. The circuit, described in the literature by Lufcy and others, is shown schematically in Fig. 1(A).[2–4] An explanation of this triggering is presented based upon a type of reverse-slope magnetic-loop operation not previously described in the magnetic-amplifier literature (see acknowledgment). Figs. 2(A) and (B) are two commonly used models of the dynamic loops of "square-loop" magnetic-core materials. The paper shows that neither model predicts the observed triggering but that a loop having the "reverse slope" of Fig. 2(C) readily predicts the instability. In Fig. 2(C) the lower minor loop lies to the right of upper minor loop, and lines connecting their centers or flanks would have a negative or reverse slope. The reality of this reverse-slope phenomenon has been determined experimentally, and verifying data are presented. The reader is cautioned that the reverse-slope phenomenon applies only to minor hysteresis loops and not to major loops operating over the entire range from positive to negative saturation. The reader should also be aware that no model of minor- or major-loop operation can be expected to apply to other than a limited range of exciting conditions.

Nomenclature

e_c, E_{cm}, E_c = instantaneous, peak, and rms control voltage
e_s, E_{sm}, E_s = instantaneous, peak, and rms supply voltage
i_c = control current
i_{L1}, i_{L2} = load currents in R_{L1} and R_{L2}
i_{G1}, i_{G2} = currents in gate windings of either core
i_{r1}, i_{r2} = currents in the reset circuit
N_c = control turns
N_g = gate or load turns
N_m = pickoff turns for induced voltage measurement
$(Ni)_1$, $(Ni)_2$ = total magnetic intensity applied to either core, ampere-turns: $(Ni)_1 = -N_c i_c + N_g i_{g1}$, $(Ni)_2 = N_c i_c + N_g i_{g2}$
R_c = control circuit resistance
R_{L1}, R_{L2} = load resistors for case of split load
R_L = load resistor $= R_{L1} + R_{L2}$ in case of split load
R_{mc}, R_{mr}, R_{ml} = measuring resistors in control, reset, and load circuits respectively (Fig. 10)
R_{r1}, R_{r2} = reset resistors
R_S = resistance in series with bridge or output circuit
R_{wc} = winding resistance of N_c
R_{wg} = winding resistance of N_g
V_{g1}, V_{g2} = voltage induced in gate windings N_g of either core
V_L, $\bar{V}_L$ = instantaneous and average load voltage across R_L or R_{L1} and R_{L2} combined
θ_1, θ_2 = firing or saturation angles of cores *1* and *2*
ψ = core flux
RHWACDC = reversible half-wave a-c, d-c
RHWAC = reversible half-wave a-c
RHWDC = reversible half-wave d-c

Reversible Half-Wave Magnetic Amplifier, Bridge and Center-Tap Types

Paper 58-776, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted March 11, 1958; made available for printing April 1, 1958.

D. L. MCMURTRIE and J. P. WARD are with the Raytheon Manufacturing Company, Wayland, Mass.

As the manuscript of this paper was in final preparation, the authors encountered a paper by L. A. Finzi and D. L. Critchlow.[1] As part of a general treatment of the reset process under various conditions, their paper describes magnetic-minor-loop operation similar to that reported in this paper and connects this loop operation with certain types of amplifier triggering. Happily, the amplifiers dealt with and the details of the triggering are not the same as those of this paper. The authors are pleased that this paper has come to their attention and wish to give due credit to the fine work of F. A. Finzi and D. L. Critchlow.

Fig. 3 (right). Different types of reversible half-wave output

type of circuit has found extensive use as a servoamplifier because of its reversible output and fast response.* Operation of the circuit has been adequately described in the references cited previously, and the description given here is very brief.

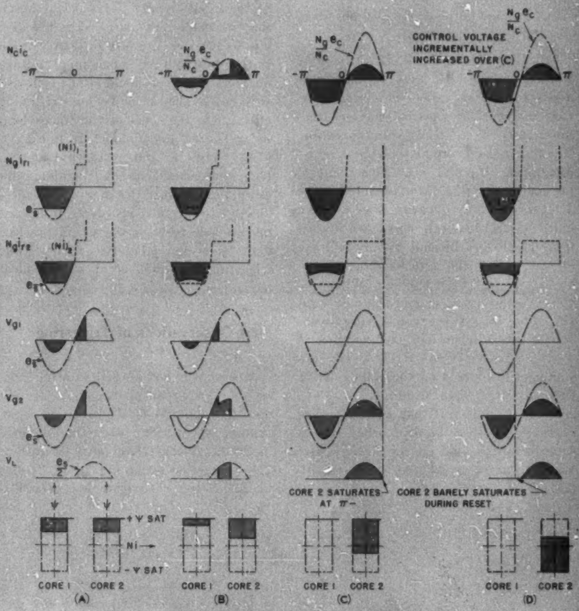
The waveforms shown in Fig. 4 indicate the operation of the circuit of Fig. 1(B) at various output levels assuming ideal rectangular-loop operation, ideal rectifiers, and zero winding resistance. It is also assumed that the control circuit resistance is matched to the reset resistance such that $R_c(N_g/N_c)^2=2R_r$. The waveforms of V_L show the nature of the output pulses which have d-c and fundamental frequency components (and higher harmonics).* Pulses of the opposite polarity would be produced if the phase of the control signal were reversed causing cores *1* and *2* to change places. In all cases, the negative or reset portions of coil voltages V_{g1} and V_{g2} are dictated by combined reset and control circuit action, the load circuit being kept open-circuited by its rectifiers. Positive or prefire voltage is dictated by the load circuit, the reset circuit being open-circuited by its rectifiers, and the control circuit having little effect because of its high impedance relative to the load circuit: i.e., $R_s,\ R_{L1},\ R_{L2} << R_r,\ R_c(N_g/N_c)^2$. For zero input and output the reset resistors are adjusted to cause approximately two thirds of the supply voltage area to appear across each resistor and one third across each gate winding during reset. The cores then saturate at approximately 50 degrees on the following positive half-cycle.

Determination of the instantaneous values of the control and reset current and voltage at finite levels of input and output becomes somewhat involved algebraically although the circuit is piecewise linear and the circuit equations not difficult to set up. The way in which the control voltage affects the reset of both cores is best seen by redrawing the circuit of Fig. 1(B) to show only those portions normally active during the reset half-cycle. This is done in Fig. 5. The three loop equations can readily be written remembering that in addition to the Kirchhoff equations there are also the $\psi_{gs}Ni$ or $V_{gs}i$ equations of the reactors (graphically presented by the loop paths).

The reset equations are not set up and solved, but the following observations should be sufficient to allow the reader to check the solutions graphically presented in Fig. 4:

1. The voltage and current equations are

$$V_{g1}=e_s-i_{r1}R_{r1} \qquad R_{r1}=R_{r2}=R_r$$
$$V_{g2}=e_s-i_{r2}R_{r2}$$
$$V_{g2}-V_{g1}=(e_c-i_cR_c)(N_g/N_c)$$
$$\left.\begin{array}{l} N_gi_{r1}-N_ci_c=(Ni)_1 \\ N_gi_{r2}+N_ci_c=(Ni)_2 \end{array}\right\}$$
...must conform to the magnetic loops and must be constant while each core is resetting



NOTES: 1. ASSUMED THAT $R_{wg}=0, R_s=R_{L1}, R_{L1} << R_{r1}, R_{r2}$

2. SCALE IS SUCH THAT CURRENT WAVEFORMS MAY ALSO BE INTERPRETED AS VOLTAGES $\frac{N_g}{N_c}i_cR_c, i_{r1}R_r, i_{r2}R_r$

A—Zero output B—Medium output
C—Almost full output D—Slightly beyond full output

---

* It would be best to characterize this circuit as "half-wave reversible a-c, reversible d-c output." There are actually two other types of reversible half-wave circuits: half-wave reversible a-c, nonreversible d-c output; and half-wave nonreversible a-c, reversible d-c output. The authors favor the shorthand notation RHWACDC, RHWAC, and RHWDC for these three types of circuits respectively. Fig. 3 illustrates these different possible output characteristics.

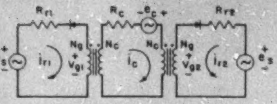

Fig. 5. Equivalent circuit during the negative or reset half-cycle

2. With control ampere-turns adding to reset ampere-turns in one core and subtracting in the other, one core will reach the shoulder of its loop and begin to reset before the other.

3. Operation is piecewise linear with three possible "pieces" or zones of linear operation from $-\pi$ to $-\pi/2(-\pi/2$ to 0 is symmetric to $-\pi$ to $-\pi/2$ unless saturation occurs).

These zones are:

a. both cores traveling along the top of the loops with all windings appearing as short circuits.

b. one core resetting with voltage across it while the other is still traveling along the top of its loop with its windings appearing as short circuits.

c. both cores resetting and absorbing voltage.

It is, of course, basic that the gate winding voltages V_{g1} and V_{g2} have zero average value or, expressed another way, that the reset and prefire voltage areas must be equal in steady-state operation. The flux in each core may be obtained by integrating V_{g1} and V_{g2}. One point of particular interest may be observed in the V_{g2} waveforms. During the positive half-cycle when both cores are unsaturated, nearly the full supply voltage appears across the gate windings of the two cores, and $V_{g1}=V_{g2}\doteq e_s$. When one core is saturated (core *1* in this case) and the other is not, the voltage appearing across the unsaturated gate winding is $V_{g2}=[(R_{L1}+R_{wg})/(R_s+R_{L1}+R_{wg})]e_s$ assuming, as is done, that the inductance of the saturated gate windings drops to zero. It is apparent that V_{g2} can either continue smoothly or drop when core *1* saturates depending on the series resistance R_s and on whether $(R_{L1}+R_{wg})/(R_s+R_{L1}+R_{wg})\leq 1$. In Fig. 4, it is assumed that $R_{wg}=0$ and $R_{L1}/(R_s+R_{L1})\doteq 0.5$. It is found that this ratio $(R_{L1}+R_{wg})/(R_s+R_{L1}+R_{wg})$ has important consequences on triggering action.

Maximum output occurs when one core fires at 180 degrees and the other fires at 0 degrees. If one core reaches 180 degrees before the other reaches 0 degrees (or vice versa), the gain of the circuit is reduced at larger values of output as shown in Fig. 6(B). It should be noted that after one of the cores reaches a firing angle of 180 degrees, point *1* in Figs. 6(A) and (B), it proceeds to saturate on the reset half-cycle with the consequence that its dynamic operating loop changes from clinging-to-positive saturation to clinging-to-negative saturation as shown in Fig. 4(D). This change, which is quite similar to that occurring in the a-c doubler and other types of circuits, is accompanied by a time lag depending upon the ratio of the minor-loop height to 2 ψ_{sat} and to the magnitude of the input signal.[6] This delay, which may be made quite large, does not give rise to any discontinuity or double value in the static output versus input voltage characteristic and should not be confused with such discontinuity or triggering effect. On the basis of the square-loop model (or rectilinear model (B) in Fig. 1), ideal rectifiers, and resistive load, no triggering should occur. Winding and stray capacitance, leakage inductance, and other miscellaneous effects, which are unavoidable to some degree, in practice may give unpredictable results, but triggering does not occur in the ideal model.

First Observations of Triggering

Anyone who has worked with the half-wave bridge circuit or its equivalents has probably observed at least a slight amount of triggering when the amplifier output is reduced from oversaturation. This action is shown in Fig. 7(A). In one sense, however, the triggering is generally not a matter of practical importance to the equipment designer who, therefore, regretfully decides to forget about the phenomenon and go on to deal with more pressing problems. The fact is that operation in the saturated region must be avoided altogether if one is to preserve fast response.[2,4] It is often necessary to avoid oversaturation because of a decrease in output which may occur in this region as shown by dashed lines in Fig. 6. Limiting may be accomplished by limiting the input signal or by other more subtle means (limiting the amount of iron in the cores, for example). However accomplished, the limiting also elminates the triggering (generally). When the triggering is thus avoided, and as long as the triggering is rather minor to begin with, as it generally is, the designer is tempted to ignore the triggering, ascribing it to a number of vague "possibilities" affected by a host of nonideal conditions such as nonideal core leakage inductance, rectifier leakage and capacitance, finite nonlinear rectifier forward resistance, winding and stray capacitance, bridge rectifier backfiring during reset, etc. There is generally no shortage of possible causes of minor discrepancies in the operation of most magnetic-amplifier circuits, and the way in which positive feedback or inductive loading, intentional or unintentional, can cause instability is well described in the literature.[7-10]

Thus it was that triggering was observed, eliminated, and put out of mind on several occasions by the authors. Certain circuit changes were then made, however, which yielded triggering effects too enormous to ignore (see Fig. 7). Specifically it was found that an increase in the series resistor R_s or, more properly, in the ratio R_s/R_L increases the triggering proportionately and may increase it to the point where the circuit is simply bistable, i.e., yields full output of either one polarity or the other with no choice of output levels in between.

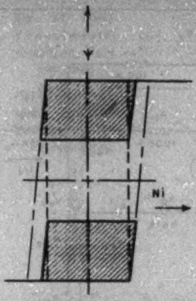

Fig. 9 (above). Magnetic core model from Fig. 8 of reference 16

Why one should wish to increase R_s is not an issue here, but it may be stated parenthetically that R_s may be used to limit circulating current in the load when both cores are saturated simultaneously and also that the amplifier gain may be increased as R_s is increased provided one is also free to modify and optimize turns and wire size on the gate windings. This latter statement is not evident without detailed analysis (to which there is no reference in the literature), but may be derived in a straightforward way none the less.

Triggering Explanation

Investigation has proved the reasons of triggering to be quite simple and to be entirely divorced from positive feedback or inductive loading. The causes are two fold. The first essential feature is that the minor hysteresis loops exhibit a shift similar to that shown in Fig. 2(C). This is confirmed beyond question by experimental data. The second essential feature is that the resistance in the reset circuit be large compared with the unsaturated impedance of the gate or reset winding. Under these conditions it is simple to show that triggering must occur, and experimental confirmation has been obtained. It can also be shown that triggering should and does occur if the control circuit is opened and output is controlled by varying one of the reset resistors. In fact, the underlying phenomenon causing triggering can be confirmed even further by observing its action in a single core.

Theoretical Considerations

Waveforms based on an idealized core model, ideal rectifiers, and a value of $(R_{L1}+R_{wg})/(R_s+R_{L1}+R_{wg}) \doteq 0.5$ are shown in Figs. 8(A) and (B). The core model used is shown in the lower part of figures. The minor magnetic loops remain rectangular but the ones clinging to $-\psi_{sat}$ are shifted approximately 10% of their total width in the $+(Ni)$ direction. At zero output the circuit will operate in the same way as shown previously in Fig. 4(A). The control circuit resistance is assumed to be matched to the reset resistance such that $R_c(N_g/N_c)^2=2R_r$. The solid waveforms of Fig. 8(A) show the case in which core *1* is firing at 90 degrees while core *2* is just firing at 180 degrees with the dynamic loop clinging to $+\psi_{sat}$.* The circuit operates in quite the same manner as explained previously in connection with Fig. 3. The total ampere-turns of core 2 have been sketched to show its correlation with the hysteresis loop.

Suppose that the control voltage is increased by an incremental amount. During the first reset half-cycle the voltage of V_{g2} is increased incrementally while the subsequent prefire voltage remains the same, being at its maximum value initially. If the core operated along the sides of a perfectly rectangular major loop, the operating path would merely circle slowly from $+\psi_{sat}$ to $-\psi_{sat}$ and make the transition shown in Figs. 4(C) and (D). Once at the bottom of the loop the core would barely saturate on the reset half-cycle so that reset and prefire areas again become equal and a new steady-state condition would be established without triggering. If the minor loop at $-\psi_{sat}$ is shifted to the right, however, the results are quite different. The total reset current required is reduced, the voltage drop across the reset resistance is decreased, and the peak reset voltage across the gate winding is increased as the operating path circles to the bottom of the loop. The prefire voltage does not change appreciably despite the increased prefire ampere-turns because of the low impedance of the load circuit, which means that $V_{g2} \doteq 0.5e_s$ even if the prefire current and the *IR* drops in R_s and R_{wg} are doubled or tripled. With the prefire voltage remaining approximately unchanged, the reset voltage area cannot increase in the steady state. Since the peak reset voltage has increased, there is no alternative but for the core to saturate at some angle appreciably before the end of the half-cycle in order to preserve the necessary equality of prefire and reset voltage areas. Note that the output remains unchanged at its maximum value and that triggering has occurred only in the reset voltage waveform.

---

* In general one would wish to have one core reach 0 degree at the same time that the other reaches 180 degrees, but the tendency to trigger is observed regardless.

Fig. 10. Experimental circuit

If the control voltage is decreased now, output voltage triggering will occur, but not immediately. The reset voltage will gradually be decreased in peak amplitude while the core saturates later in the half-cycle and the reset voltage area remains constant. This continues until the reset saturation angle is pushed to 0 degrees. Throughout the process the output remains unchanged at its maximum level. On the output-input characteristic of Fig. 7(B), the circuit is traversing the path from point *1* to *2*. Point *2*, the point at which the control has been decreased until reset saturation occurs incrementally short of 0 degrees, is shown in the solid curves of Fig. 8(B). A further decrease in the control voltage sends the core operational path cycling up to $+\psi_{sat}$. If the core operated along the sides of a rectangular major loop, the process would be accompanied by a time delay but no triggering. For the minor loop shifted to the left, however, output triggering must occur. With the required reset current increased, the available reset peak voltage and voltage area across the gate winding is decreased. Since the prefire voltage area must equal the reset voltage area, in the steady state, the core must now saturate at some angle in advance of 180 degrees, and the output voltage makes a corresponding jump decrease out of saturation.

The sequence of events in the foregoing two paragraphs is not quite the whole story. Any triggering effect that begins to be exhibited in either the reset or prefire voltage of one core must necessarily alter the reset and prefire of the other core and be itself altered in turn because of the control circuit coupling. The interaction modifies the triggering action only slightly and the final results are readily sketched as shown.

Having gone thus far in the explanation of triggering, the core model is reexamined for a moment. The model used has perfectly rectangular minor loops. The one essential feature for triggering, however, is the shift in the left or reset side of the loop. It should be clear that this side of the loop may be vertical or sloping or may even change slope but triggering will occur so long as the average ampere-turns during reset show a decrease in going from upper to lower minor-loop operation. It might be thought that all necessary information is contained in the upper or lower loops alone, one set being a mere reflection of the other. This would be true except for the difference in exciting conditions during the reset and firing half-cycle. The effect of the different exciting conditions is brought out in the experimental data to follow, and may also be seen in minor loops of completely different character, as shown in references 10 and 11, despite the similarity of the core material and the major d-c and a-c magnetic loops. The width of any magnetic loop is very much a function of at least the first derivative of the flux (among other things not well understood) and is therefore very much a function of the exciting voltage waveform and source impedance.[13–15] An interesting paper by Batdorf and Johnson presents evidence of d-c loop operation as shown in Fig. 9 which is taken from their paper.[16] Here one notices the same narrowing of the magnetic loop as one travels up or down from starting points other than the fully saturated condition. The authors show that bistable operation will appear in the doubler magnetic amplifier if these same general loop characteristics may be extended to a-c operation. In the triggering phenomenon being dealt with here, however narrowing of the loops is not a sufficient condition for triggering. As pointed out in the foregoing, the necessary conditions are: 1. that the left (reset) side of the lower minor loops must not only be shifted but must be shifted to the right of the corresponding upper loop, and 2. that the reset resistance must be sufficiently large and support a sufficiently large portion of the supply voltage so that the decrease in reset current allows a significantly larger reset voltage to appear across the reactor winding. Thus, when the major loop has a sloping parallelogram characteristic, shifts in the minor loop may occur and not cause triggering. Interestingly, this agrees with the general observation that instability in most types of magnetic amplifiers is more pronounced when magnetic materials having more nearly rectangular major-loop characteristics are used.

EXPERIMENTAL CONFIRMATION

In the initial search for an explanation of the triggering phenomenon, which seemed to persist despite gradual elimination of other postulated causes, the authors experimented on paper with the effects of different core models and arrived at the reverse-slope effect, just reviewed, as a possible cause of triggering.

Experimental evidence was then sought to confirm or reject this possible explanation. Experimental corroboration is not immediately evident since one cannot ordinarily view the total core ampere-turns waveforms $(Ni)_1$ and $(Ni)_2$ of Figs. 8(A) and (B). The experimental circuit of Fig. 10 was soon arranged wherein current-measuring resistors proportional to the winding turns were placed in the control and load circuits. If one uses the resistor values shown in Fig. 10 and connects the control and output circuits along the dashed line, the voltage *OB* is proportional to the total ampere-turns around core *1*. In a similar fashion (but using a different control-load circuit connection) the total ampere-turns on core *2* may be obtained by a single voltage waveform.

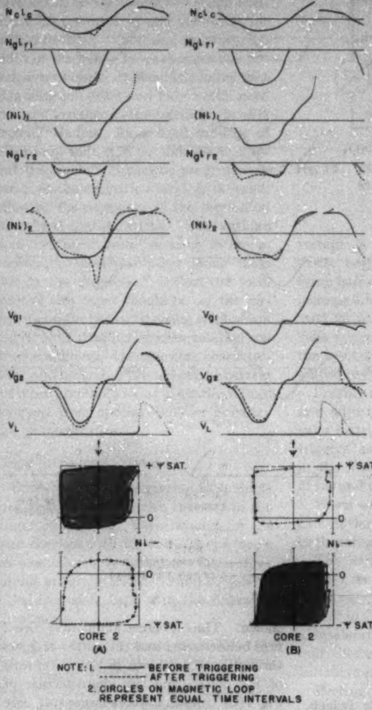

Fig. 11 (left). Experimental waveforms, R_s = 100 ohms

A—Output entering saturation
B—Output leaving saturation

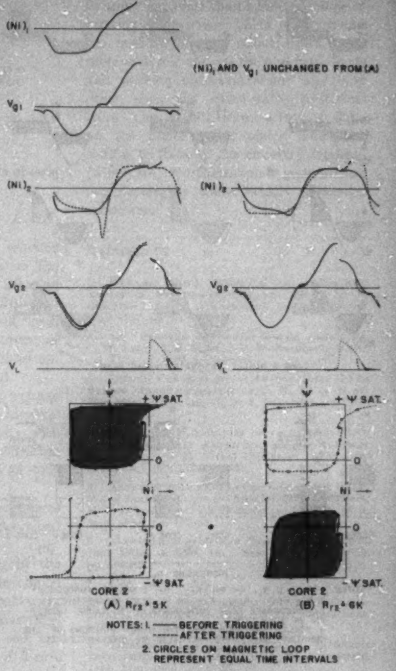

Fig. 12 (right). Experimental waveforms, R_s = 100 ohms. Control circuit open; output controlled by varying R_{r2}

A—Output entering saturation
B—Output leaving saturation

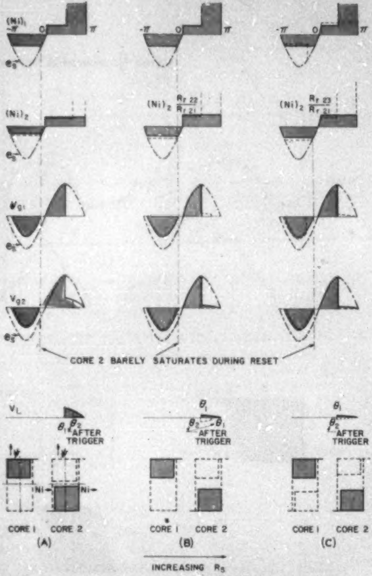
Of course, the individual winding currents may be obtained and added graphically, but the single voltage trace on an oscilloscope gives a convenient, immediate continuous monitor of the dynamic loop width while making exploratory circuit parameter changes. Pickoff windings were used to obtain coil voltages unaffected by *IR* drops. Fig. 11 presents waveforms, taken from oscilloscope photographs, together with magnetic-loop paths derived from the current and voltage (graphically integrated) waveforms. These waveforms should be checked against those of the theoretical model shown in Fig. 8. The data confirm the reverse-slope effect quite nicely. The jog in the rising portion of the magnetic loop is of minor importance. It results from the sudden drop in voltage across the load winding of core *2* as core *1* saturates. As previously discussed, the general shape of the loop during the firing or positive half-cycle has negligible effect on circuit operation. The jog does serve to show that the upper and lower loops need not be symmetric to one another.

Output Controlled by Varying Reset Resistance

As further confirmation of the cause of triggering it was decided to leave the control circuit open and look for the triggering effect with the output controlled by varying one of the reset resistors. Reset voltage across a gate winding can be effectually varied in this manner to control the output voltage of the amplifier. This method of operation has two advantages. First, it eliminates the possibility of control circuit interaction as a cause of triggering. Second, it allows the total coil current to be observed across a single current-measuring resistor and eliminates the possibility of incorrect scaling of ampere-turns contributions of the control circuit to the total ampere-turns because of an erroneous turns count, etc. Output triggering is predicted much as in the previous case except that the output is now a function of one of the reset resistances rather than control voltage. The waveforms of Fig. 12 exhibit the triggering action clearly and again confirm the reverse-slop effect in the magnetic loop. The fact that these waveforms were obtained with the control circuit open clearly proves that the control circuit interaction plays no essential role in the triggering effect. With the output going into saturation, triggering tends to occur somewhat before the firing angle of core *2* reaches 180 degrees as shown in Fig. 12(A) causing a noticeable discontinuity in the output.

Effect of Large Series Resistance R_g

The case dealt with thus far is $(R_{L1}+R_{wg})/(R_s+R_{L1}+R_{wg})\doteq 0.5-0.6$. After the first core saturates during the positive half-cycle, the voltage across the load winding of the second drops from e_s to approximately $(0.5-0.6)e_s$. The effect of varying R_g is examined now. Experimentally it is found that large values of R_s or R_s/R_{L1} aggravate the triggering action and can even cause the output to jump through zero as shown in Fig. 7(C).



NOTES: 1. $R_{wg} = 0$, $R_{L1} << R_{r1}, R_{r2}$. R_{r1} CONSTANT THROUGHOUT.
2. $R_{r2} = R_{r21}, R_{r22}, R_{r23}$ IN (A) (B) (C) RESPECTIVELY. R_{r2} INCREASED ONLY INCREMENTALLY TO CAUSE TRIGGERING IN EACH CASE.
3. SCALES ARE SUCH THAT THE RESET PORTIONS OF THE CURRENT WAVEFORMS MAY ALSO BE INTERPRETED AS $i_{r1} R_{r1}$ AND $i_{r2} R_{r2}$.

Fig. 13 (left). Theoretical waveforms. Triggering with increased series resistance. Control circuit open; output controlled by varying R_{r2}

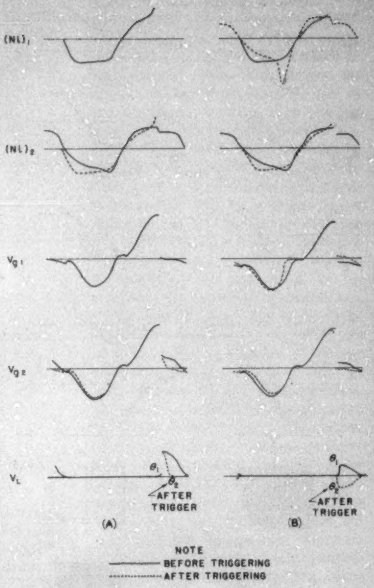


Fig. 14 (right). Experimental waveforms. Triggering with increased series resistance. Control circuit open; output controlled by varying R_{r2}
A—R_s = 500 ohms
B—R_s = 1,200 ohms

The reasons are not difficult to see. In Fig. 13 waveforms are drawn to show the effect of increased R_S on the triggering which occurs in decreasing the output from saturation. In this case the control circuit is open with the output controlled by varing reset resistance R_{r2}. At zero output any change in the series resistance has no effect on the circuit other than to reduce the current which flows after both cores are saturated: assuming, of course, that magnetizing current through R_S gives negligible voltage drop. As the output is varied, whether by supplying a control voltage or by varying one of the reset resistors, the effect of the series resistor becomes evident. R_S can have no effect on the reset process in either case since the load circuit is kept open-circuited by its rectifiers during the reset half-cycle. On the positive half-cycle R_s makes itself felt after the first core saturates (core *1* at θ_1, in this case). At this time the voltage across the other core drops to $(R_{L1}+R_{wg})/(R_s+R_{L1}+R_{wg})e_s$ as discussed in previous sections. Since the prefire voltage area of this second core must equal the reset voltage area of the preceding half-cycle (which has been unaffected by R_s), it follows that the lower the voltage after θ_1, the later in the cycle will the core saturate. It also means that the greater will be the angular jump in V_{g2} (and the greater the change in output pulse width) for any abrupt change in reset during triggering. It should be noted that the presence of R_s decreases the magnitude of the output pulse and that in terms of output pulse area the triggering is not necessarily greater.

As long as the firing angle θ_2 of the second core does not attempt to trigger to less than θ_1, V_{g1} remains unchanged. If R_s is made larger, the unique circumstance shown in Fig. 13(B) is encountered. Here the prefire voltage cannot decrease sufficiently unless it saturates before the other core fires at θ_1. It does just this. Now, however, V_{g1} has been tampered with since its value must drop after its companion saturates. Since its reset has been altered little or not at all, the prefire voltage area must stay the same. The only way in which this can happen is for core *1* to saturate later in the cycle as shown. Thus it comes about that core *2* fires before core *1* and the output triggers through zero as shown in the waveforms of Fig. 13(B) and the characteristic of Fig. 7(C). As R_s is made larger still, core *1* will saturate later in the cycle until it reaches 180 degrees. Finally the reset voltage of core *1* exceeds the prefire voltage even though the core does not fire until 180 degrees. Core *1* must then travel down the loop and saturate during reset. This case is shown in Fig. 13(C).

Experimental waveforms taken from oscilloscope photographs are shown in Fig. 14. These waveforms agree well with the theoretical ones of Figs. 13(A) and (C).

EFFECT OF VARYING EXCITATION LEVEL

One would expect that the height of the the minor loops in relation to the major loops might have a great bearing on the magnitude of the sideways shift of the minor loops and on the triggering effects just described. Specifically, one might expect the shift to decrease or disappear as the size of the minor loop at maximum output approaches that of the major loop, the condition generally described as "normal excitation." Laboratory tests indicate that the triggering does decrease although in many instances triggering is observed at or very close to normal excitation as reported in the following for single-core tests. The way in which the width of the minor loops changes has not been determined. It should be noted that triggering intensity and loop width need not vary together as the excitation level is altered. Indeed, for a fixed amount of minor-loop shift, it is not difficult to show that triggering will become progressively worse as the excitation level is reduced, following the reasoning of the section on theoretical considerations. The authors have refrained from making intensive loop-width experimentation along these lines in the conviction: 1. that the focal point of this paper should be on the circuitry and the basic triggering mechanism and 2. that detailed studies relating exciting conditions, dynamic core characteristics, and basic core physics can be carried out more profitably along generalized lines divorced from special amplifier circuitry and characteristics.

Tests on Single Cores

Tests to observe triggering in a single core were conducted with the core in the circuit of Fig. 15. Three wound toroids were checked with 60- and 400-cps (cycle per second) supply voltages. These three toroids are grain-oriented 2-mil 50%-50% nickel-iron-alloy tape with the following dimensions:

Core *1*...1-inch ID (inside diameter), $1^1/_4$-inch OD (outside diameter), 1/4-inch height, ID/OD ratio = 0.8
Core *2*...$1^1/_2$-inch ID, 2-inch OD, 1-inch height, ID/OD ratio = 0.75
Core *3*...$1^1/_4$-inch ID, 1.875-inch OD, 1/2-inch height, ID/OD ratio = 0.668

With the cores set up as in Fig. 15, 60-cps normal excitation swings the cores from positive to negative saturation. Under this condition the core does not enter the saturated region, and the usual square wave of exciting current is observed across R_2. Next the reset supply voltage E_r is decreased by 3%. A small trigger is observed in the current waveform during the positive or firing half-cycle. The trigger consists of a peak (at the end of the firing half-cycle) approximately 133% higher than the exciting level and 18 degrees in duration. The supply voltage is then reduced 30% below the normal excitation level. The current waveform across R_2 shows saturation on the reset half-cycle. As the reset voltage is reduced, a point is reached where triggering into saturation on the firing half-cycle takes place with duration increased to 36 degrees and amplitude at least 20 times the exciting current level. This trigger, with careful adjustment of the reset voltage magnitude, can be observed to take as long as 1 second.

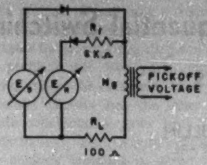

Fig. 15. Experimental circuit used to observe triggering in a single core

Further reduction of the supply voltage and adjustment of the reset voltage results in triggers of greater severity with triggers as large as 90-degree duration in the firing half-cycle recorded at 40% of normal excitation.

When excited at 400 cps, these cores exhibit the same phenomenon as described in the foregoing.

The explanation of triggering in the single core is the same as that developed previously for the reversible half-wave circuit in the section entitled "Theoretical Considerations." In the single-core circuit, however, any possibility of 2-core interaction is eliminated as a cause of triggering. The tests at various levels of excitation show that the minor-loop shift is not a phenomenon restricted to reduced excitation but may occur for minor loops which are very nearly as large as the major loop itself.

Conclusions

A new mode of magnetic-amplifier instability has been described and attributed to a reverse-slope effect in the locus of the minor magnetic loops of 50%-50% nickel-iron rectangular-loop core material. Theory and supporting experimental data have been presented to show that this unusual loop effect is actually present and is responsible for triggering of the amplifier as its output voltage enters and leaves its saturated maximum level. The reader is again cautioned that no model of minor- or major-loop operation can be expected to apply for other than a limited range of exciting conditions. There is, or should be, nothing strange about bows, jags, reverse slopes, etc., in the magnetic loops and nothing universal about any loop other than the quasi-static hysteresis loop. One should expect a reverse slope on the minor loops under conditions similar to those of the circuitry reported (which are nevertheless quite general) and not necessarily under widely dissimilar conditions.

Reliable Stochastic Sequential Switching Circuits

ALBERT A. MULLIN
ASSOCIATE MEMBER AIEE

Synopsis: A procedure based upon probabilistic logics is developed for the analysis and synthesis of reliable asynchronous relay sequential switching circuits, subject to a set of statistical postulates. The reliability of a sequential circuit is measured as proportional to a logarithm of the probability of error for certain state transitions of the circuit involved. The "ces" as a unit of reliability is proposed by the author. An example of the analysis and synthesis procedure is given.

THE PURPOSE of this research is to investigate certain aspects of the nature and effects upon circuit action of a probabilistically specified malfunction attributed to the contacts used in the realization of relay asynchronous sequential circuits.

Relevant Background

At present, the principal published papers on the use of probabilistic logics as a mathematical tool for effecting the synthesis of reliable logical systems are quite recent, and two in number: the first by Von Neumann[1] and the second by Moore and Shannon.[2] Certain parts of Von Neumann's paper are a ramification and extension of the concepts contained in a paper by McCulloch and Pitts.[3] Von Neumann treats logical systems composed wholly of one or the other of two specific components. The treatment is carried out in quite a general mathematical fashion. A lower bound on the error level for each of the components of $\epsilon<1/6$ is needed in Von Neumann's model to insure receiving a more reliable automatum by the proper M-truplication of its components.

Moore and Shannon explicitly consider relays as components used to construct certain primarily combinational, logical systems.[2] In their model, each relay comprising the circuit is looked upon as a noisy binary information channel, which is not necessarily symmetric. Relays as components are less general than the components treated by Von Neumann. Nevertheless, many useful results still appear, since Moore and Shannon have shown that "by using a sufficiently large number of relays in the proper manner ... circuits can be built that are arbitrarily reliable, regardless of how unreliable the original relays are."

Terminology

Because of their relative simplicity, relays will be used as a vehicle for demonstrating the theory. However, it is intended that much of the theory itself be independent of specific components. The word "classical" will be used in reference to a set of deterministic (nonprobabilistic) procedures for synthesizing sequential circuits.

In two significant papers, Huffman has developed a deterministic model for synthesizing classical sequential circuits[4] and a procedure for synthesizing hazard-free classical combinational circuits. These two fundamental papers will be referred to freely by the author.[5] (An engineering textbook covering these subjects among many other topics in classical switching circuits is reference 6.)

The concept of primary and secondary relays will be carried over from the classical theory of relay sequential circuits. Thus, a primary relay in the probabilistic theory is one whose relay coil is connected directly to an input line of the circuit and a secondary relay is any other relay that is utilized in the circuit.

In the following, the author will be concerned with the probabilistic model unless a specific statement to the contrary appears.

Normally open and normally closed contacts will be defined by means of a binary information channel.[7] Such a binary channel is shown in Fig. 1, where, for example, A is the probability that a specified contact on a specified relay is open, on the hypothesis that the relay coil is de-energized.

Definitions

1. A relay contact will be called normally open if and only if $A-B>0$.
2. A relay contact will be called normally closed if and only if $A-B<0$.
3. A relay contact will be called random if and only if $A-B=0$.

From the probabilistic point of view, it may be said that normally open and normally closed contacts differ only in degree rather than in kind.

4. The conditional probability of the event A, given that the event B has occurred, denoted by $P(A|B)$, is defined as the joint probability of the events normalized to the probability of event B.

$$P(A|B)=\frac{P(A\cap B)}{P(B)}$$

5. Several events are defined to be statistically independent if the probability of occurrence of any one of them is not affected by the supplemental knowledge concerning the occurrence of any number of the remaining events. For two events A and B this may be expressed in the form $P(A|B)=P(A)$, or $P(B|A)=P(B)$. A more concise definition of statistical independence appears in reference 8.
6. The state of a sequential circuit is defined by the ordered set of 2-state variables $X_1, X_2, \ldots X_M, Y_1, Y_2 \ldots Y_N$ where X_1 is an ordered set of 2-state response variables $x_{11}, x_{12}, \ldots x_{1Q}$ of the Q contacts utilized from the primary relay $x_1, \ldots$, etc., and Y_N is an ordered set of 2-state response $Y_{N1}, Y_{N2}, \ldots Y_{NR}$ of the R contacts utilized from the secondary relay Y_N. (The significance of this abstract definition appears in the section "Analysis.")
7. A transition probability is defined as the conditional probability of the circuit going to a given state on the hypothesis that it was in a given state. As an example, $P(S_2|S_1)$ is the transition prob-

Paper 58-854, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted December 12, 1957; made available for printing April 25, 1958.

ALBERT A. MULLIN is with the University of Illinois, Urbana, Ill.

This paper is a condensed version of a master's thesis entitled "Probabilistic Logics in the Synthesis of Reliable Sequential Circuits," which was submitted on July 12, 1957, to the Electrical Engineering Department of the Massachusetts Institute of Technology, Cambridge, Mass. The author acknowledges the constructive criticism of Prof. C. E. Shannon, who supervised the thesis. However, the author accepts full responsibility for any errors. He is indebted, for the "feedback" received, to the switching circuits group of the Digital Computer Laboratory at the University of Illinois, through a series of three lectures on the subject of the paper. The author dedicates this paper to his mother and father.

ability of the circuit going to state 3, given that the circuit was in state 1.

8. A stochastic matrix is defined as a square matrix whose elements are transition probabilities. The element P_{JK} of the stochastic matrix is at the intersection of row J and column K and is identical with $P(S_K|S_J)$.

Postulates

1. Only one input line may change state at any given time and the same or another input line will not change state until the circuit settles down.

2. Each relay has only one relay coil, and will be assumed to have a defining probability for its normally open contacts so that $A \geq 0.9$ and $B \leq 0.1$. The defining probability for the normally closed contacts will be such that $A \leq 0.1$ and $B \geq 0.9$.

This assumption should not detract very seriously from the general theory, and certainly not from applications utilizing commercially available relays. However, random contacts and excessively crummy[3] (low quality) relays will be excluded from interest.

3. Each utilized contact of every relay functions as if it were statistically independent of the remaining contacts of the relay concerned.

4. When the state of excitation to a relay coil is changed, each of the contacts on the relay change their response state, once at most, according to the statistical hypothesis. Thus, malfunction due to contact bounce will not be considered.

5. On a relay whose coil has had its state of excitation changed, the probability that any two contacts change their response state simultaneously is zero.

6. The members of the set of permutations of sequence in which the utilized contacts on each relay function or malfunction are equiprobable.

Analysis

The probabilistic-logical analysis problem involves being given a specific sequential circuit which is assumed to be composed of error-prone relays whose contacts function in accordance with the foregoing postulates. The statistical error associated with the circuit action is assumed to be localized with the component relays and to be due to the M-truplication of the variables. The composition of variables introduces no noise in this case. The relay as a component should be contrasted with potential-level devices such as transistors and cryotrons, where just the opposite is true.

The problem of analyzing a sequential circuit by probabilistic-logical techniques is effected by decomposing the given analysis problem into two parts, one involving only the classical theory of sequential circuits and the other only certain manipulation laws from probability theory. Each of these less formidable analysis problems is solved in its own environment and their individual results are fused together to give the solution to the original analysis problem. Thus, the probabilistic-logical analysis procedures will be a natural generalization of the classical analysis procedures.

The following is an analysis procedure for circuits free of static hazards. (The effects of static hazards upon circuit action is deferred for the present. However, an individual treatment of the quantitative effects of static hazards upon circuit action will be given later in the paper.)

Step 1. For the present discussion, the probabilistic circuit should have no kinds of hazard present. From the given sequential circuit obtain the logic properties of the corresponding classical circuit. The corresponding classical circuit is obtained, from the probabilistic circuit by using the defining probability for each utilized contact, to ascertain whether the contact is normally open or normally closed. Then, the contact so defined is considered normally open or normally closed in the classical sense. The method developed by Huffman[4] may be used to obtain the work statement of the corresponding classical circuit. Let the circuit contain M primary relays and N secondary relays. Then, the rectangular array formed by heading the columns with all possible states for an ordered set of primary response variables, and the rows with all possible states for an ordered set of secondary response variables, is a $2^N \times 2^M$ matrix. This flow matrix[4] is sufficient to describe the circuit action for the corresponding classical circuit.

Step 2. Consider the probabilistic portion of the analysis. Suppose that the state of excitation to any single relay coil changes. The response state of each normally open or normally closed contact is no longer tightly coupled to the excitation state of its relay coil. Each contact on the relay whose coil excitation changed state may be open or closed independently of the remaining contacts.

Let the primary relay response variable x_1 be β_1-truplicated, x_2 β_2-truplicated, $\ldots$, x_M β_M-truplicated, and the secondary relay response variable y_1 α_1-truplicated, $\ldots$, y_N α_N-truplicated. The state of the probabilistic sequential circuit is defined by the ordered set

$$x_{11}, x_{12} \ldots, x_{1\beta_1}, \ldots, y_{N1}, y_{N2} \ldots y_{N\alpha_N}$$

when the specific state (0 or 1) of each of the response variables is inserted. A double subscript notation is used with each of the 2-state response variables. The first subscript refers to the correspondingly numbered relay coil involved, and the second to the particular utilized contact controlled by the state of excitation applied to that coil.

Hence, if the general probabilistic problem was described by a rectangular array constructed in a manner similar to the one used for the classical problem, a

$$2^{\sum_{j=1}^{N} \alpha_j} \times 2^{\sum_{j=1}^{M} \beta_j}$$

matrix would be sufficient to describe the circuit action. This fundamental matrix will be called the primal matrix. It contains P elements, where

$$P = 2^{\left(\sum_{j=1}^{N} \alpha_j + \sum_{j=1}^{M} \beta_j\right)}$$

Hence, the numbr of elements in the stochastic matrix is S where $S = P^2$. Thus, even for relatively simple problems, it is not feasible to solve for the complete stochastic matrix without the aid of a high-speed data-processing machine.

Consider the less ambitious problem of a very special stochastic matrix. This stochastic matrix will involve only the transitions between those states, as represented in the primal matrix, that agree with the stable states of the corresponding classical circuit. Actually, these transitions are the more important ones for many practical problems, because the corresponding classical circuit is a convenient standard for reliability.

Step 3. Proceed to find the elements of the special stochastic matrix, hereafter called "the stochastic matrix." Such matrices are computable from the defining probabilities for the contacts, the geometry of the circuit, and the set of operational postulates. The computation is done as follows:

a. Inspect the flow matrix of the corresponding classical circuit. Find all of the transitions from each of the stable states to any other stable state that can be made by the change of a single input variable. These will be called allowable transitions.

b. Inspect the primal matrix. Find all of the transition probabilities between each of the states in the primal matrix corresponding to the allowable transitions between stable states in the flow matrix.

Table I. Probability Distribution for a Sequence Series

	x_{21}	x_{22}		x_{12}	x_{11}
$\frac{(0.1)^2}{2}$	0	0	$\frac{(0.1)^2}{2}$	0	0
$\frac{(0.1)(0.9)}{2}$	0	1	$\frac{(0.1)(0.9)}{2}$	0	1
$\frac{(0.9)(0.9)}{2}$	1	1	$\frac{(0.9)(0.9)}{2}$	1	1
$\frac{(0.9)(0.1)}{2}$	1	0	$\frac{(0.9)(0.1)}{2}$	1	0

c. To become more specific, consider the typical allowable transition from stable state α to stable state β as would be represented in the flow matrix. Let state γ and state δ in the primal matrix correspond respectively to the stable state α and the stable state β in the flow matrix. Each of the response variables, from the primary relay whose excitation is changed most recently, is statistically independent of the remaining response variables.

d. Find the column λ of the primal matrix headed with the particular set of input response states corresponding to state δ.

e. The probability μ of the circuit going to a state which is in column λ of the primal matrix may be found by applying definition 5 to the response state of the contacts concerned. This involves only contacts from the primary relay whose coil excitation has been changed. Contacts from any other relay or relays do not change their response state, at least, not yet.

f. Consider the states in column λ of the primal matrix. Find the probability ν of going to state δ. The probability ν is specifically conditioned on the state being in the column λ of the primal matrix. The probability ν is found by determining the new condition of excitation to each of the secondary relay coils. If state γ and state δ are in the same row of the primal matrix, the secondary coil excitation will not change. Apply definition 5 for the new condition of secondary coil excitations as regards the secondary response variables corresponding to state δ.

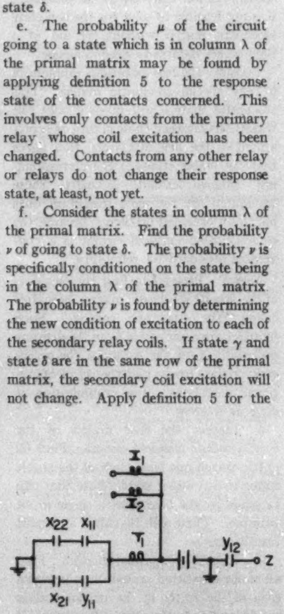

Fig. 2. Sequential circuit to be analyzed

g. The transition probability $P(\delta|\gamma)=\mu\times\nu$ is entered into the stochastic matrix at the intersection of row γ and column δ.

The transitional probabilities obtained by this procedure are lower bounds to the probabilities of receiving the output state identical to that of the corresponding classical circuit. Any transition probability corresponding to a nonallowable transition between stable states of the flow matrix will be undefined. A dash will be inserted into the stochastic matrix for this transition probability.

Let $[\text{ж}_{JK}]$ denote the stochastic matrix and $[\text{Э}_{JK}]$ denote the error matrix. Then, symbolically

$$(\text{э}_{JK})\equiv(1-\text{ж}_{JK})$$

$$\begin{bmatrix} \text{э}_{11} & \text{э}_{12} & \ldots & \text{э}_{1A} \\ \text{э}_{21} & \text{э}_{22} & \ldots & \text{э}_{2A} \\ \vdots & \vdots & \ldots & \vdots \\ \text{э}_{A1} & \text{э}_{A2} & \ldots & \text{э}_{AA} \end{bmatrix} \equiv \begin{bmatrix} (1-\text{ж}_{11}) & (1-\text{ж}_{12}) & \ldots & (1-\text{ж}_{1A}) \\ (1-\text{ж}_{21}) & (1-\text{ж}_{22}) & \ldots & (1-\text{ж}_{2A}) \\ \vdots & \vdots & \vdots & \vdots \\ (1-\text{ж}_{A1}) & (1-\text{ж}_{A2}) & \ldots & (1-\text{ж}_{AA}) \end{bmatrix} \quad (1)$$

Of course, if any particular ж_{JK} is undefined, then $\text{З}_{JK}=1-\text{ж}_{JK}$ is likewise undefined.

The measure of reliability will be taken as proportional to a logarithmic function of the error probabilities, which is used because: 1. it has intuitive significance (i.e., zero probability of error gives a "large" reliability and unity probability of error gives zero reliability); 2. it is more suggestive of the order of magnitude of the equipment needed to achieve a given reliability; and 3. it is indicative of the entropy of the error involved.

Let (P_{JK}) denote the reliability matrix. Let the mark "o" denote a binary composition law with the following property:

$$[P_{JK}]\equiv -\log_{o}[\text{э}_{JK}]$$

$$\begin{bmatrix} P_{11} & \ldots & P_{1A} \\ \vdots & \ldots & \vdots \\ P_{A1} & \ldots & P_{AA} \end{bmatrix} \equiv -\log_{o} \begin{bmatrix} \text{э}_{11} & \ldots & \text{э}_{1A} \\ \vdots & \ldots & \vdots \\ \text{э}_{A1} & \ldots & \text{э}_{AA} \end{bmatrix} \equiv \begin{bmatrix} -\log \text{э}_{11} & \ldots & -\log \text{э}_{1A} \\ \vdots & \ldots & \vdots \\ -\log \text{э}_{A1} & \ldots & -\log \text{э}_{AA} \end{bmatrix} \quad (2)$$

Since the stochastic matrix gave lower bounds to the probabilities of obtaining an output state agreeing with the corresponding classical circuit, the reliability matrix is a lower bound for the reliability with which this circuit action is obtained.

A specific base to the logarithmic measure of reliability has not yet been made. The author proposes using logarithms to the base 2 and calling the unit of reliability the "ces," in honor of Prof. C. E. Shannon, who has carried out considerable fundamental research in the field of reliable communication.

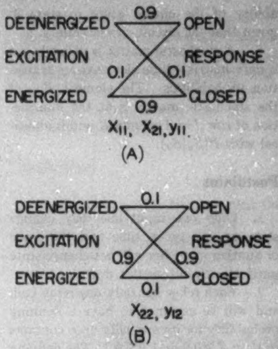

Fig. 3. Binary symmetric channel used for defining contacts shown in circuit of Fig. 2

A—Normally open contacts
B—Normally closed contacts

If the elements of the reliability matrix are not too much dispersed, a useful measure of reliability for circuit action is the single number $P_0=\min P_{JK}$.

Static Hazards

Let a sequential circuit utilize K contacts from a relay A_1. By the "sequence-series on the relay A_1" is meant the set comprised of the $(K!)$ permutations of the ordered set of utilized contacts A_{11}, A_{12}, …, A_{1K} where each of the permutations contains 2^K members. Each permutation corresponds to the time sequence in which the K utilized contacts from relay A_1, either function in accordance with the classical circuit or malfunction. The 2^K members of each permutation is the number of ways in which the K utilized contacts either function or

malfunction. The probability distribution over the ensemble of $2^X \times K!$ sequence-series may be found by applying postulates 3 and 6. Table I shows an ensemble of sequence series for $K=2$, for a normally open contact with a defining probability of $A=0.9$ and $B=0.1$.

The actual procedure involved in analyzing the effects of static hazards upon the reliability of circuit action is as follows:

1. Take the given sequential circuit and find the corresponding classical circuit.

2. Inspect the excitation (Y) matrix[4] for the control of the secondary relay coils of this classical circuit for any static hazards. This may be done by a method developed by Huffman.[5]

3. Transitions between states of the primal matrix, which correspond to allowable transitions in the flow matrix for which a static hazard can be present, must be re-evaluated. By using the defining probabilities for the utilized contacts on the primary relay, the probability distribution over the ensemble of sequence series is found. Let φ be the sum of the probabilities of those members of the sequence-series which correspond tò the condition of no hazards nor malfunction. Then, 3 where $3 = 1-\varphi$ is the probability of error due to the effects of static hazards and M-truplication of variables for the particular sequence involved. This error probability is substituted into the error matrix.

4. If, after treating the primary relay whose change of excitation involves a static hazard, any secondary response of contacts involves a static hazard, this is treated by finding the probability distribution over the ensemble of sequence series for the utilized contacts on the secondary relay involved.

5	..	1.54	3.32	..	..	..
6	1.54	..	..	3.32	..	..

P

Let A equal the probability of error due to static hazards and the M-truplication of variables in the primary relay, and let B equal the probability of error due to static hazards and the M-truplication of variables in the secondary relay. The probability B is conditioned on the effects of the primary relay. Then, the probability C of at least one error for the state transition described is $C=A+B-A\times B$.

For this more general condition, C is substituted into the error matrix. If the corresponding classical circuit is free of static because all the prime implicant tie sets and cut sets have been added,[8] the probabilistic circuit can still have error due to the effects of static hazards. This follows because the added prime implicant tie sets and cut sets are subject to malfunction in the probabilistic circuit in accordance with the statistical postulates.

It can be shown fundamentally that an added prime implicant tie set increases the probability of having at least one tie set through the network. However, it decreases the probability of having at least one cut set. Thus, an added prime implicant tie set can increase the probability of error, due to the M-truplication of variables, for certain state transitions. The added prime implicant tie set will decrease the probability of error due to the effects of static hazards.

EXAMPLE OF ANALYSIS PROCEDURE

Consider the sequential circuit shown in Fig. 2. The defining probabilities for each of the contacts are given in Fig. 3(A) and (B). An excitation and flow matrix for the corresponding classical circuit is given in Table II. The word statement of the logical properties of the corresponding classical circuit shown in Fig. 2 is, on a transmission basis, the following: $Z=0$ if $X_1, X_2=1, 0$, or if either $X_1, X_2=0, 1$, or $X_1, X_2=1, 1$ provided that relay X_1 was energized before X_2.

An inspection of the excitation and flow matrices shown in Table II indicates that a static hazard is present in the transition of states two⟷four.

Table III shows the reliability matrix for the circuit shown in Fig. 2 with respect to the flow matrix shown in Table II. The elements of the reliability matrix were calculated by using the rules of step 3 of the analysis procedure, together with the rules in the section "Static Hazards."

Synthesis

The probabilistic logical synthesis problem involves being given a description of a specified logic property, the statistical properties of the contacts of the relays available, and the lower bound for the set of defined elements of the reliability matrix.

The objective of the synthesis procedure is to synthesize a relay circuit subject to certain constraints. The design should realize the specified logic property so that if an analysis of the resulting circuit is made, no coefficient of the reliability matrix will be less than the a priori lower bound. For practical purpose, two other kinds of constraints will be placed upon the nature of the relays employed in the circuit to be designed. The first kind of constraint will have to do with the quality of the individual relays. The second will have to do with the total quantity of the equipment involved.

The purpose of the first kind of constraint is to facilitate the obtaining of some specific results without too much effort. This constraint will consist of applying postulate 2 and making B equal to $1-A$ in Fig. 1. The latter condition makes the defining channel for the contacts symmetrical, as shown in Fig. 4(A) and (B).

The purpose of the second kind of constraint is to narrow the class of possible solutions to the synthesis problem by means of an economy condition. The

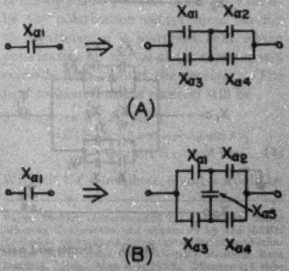

Fig. 5. A—Series-parallel network transformation. B—Bridge network transformation

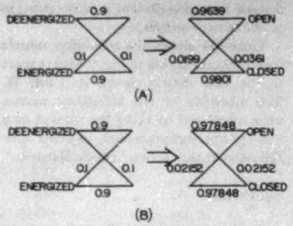

Fig. 6. Transformation of channels

A—Corresponding to Fig. 5(A)
B—Corresponding to Fig. 5(B)

economy condition will be aimed at either minimizing the number of contacts or the number of relays utilized in the circuit design.

The detailed procedure for undertaking the synthesis is as follows:

Step 1. From the specified logic properties of the problem, synthesize a minimal classical sequential circuit. If the classical circuit contains redundant secondary relays or contacts, in general, these will constitute an error producing redundancy. The classical circuit is to serve as a skeleton which is to be clothed with error reducing redundancy.

Step 2. Consider each normally open contact in the classical circuit from step 1. Assume that each of these contacts functions according to the statistics of the noisy symmetrical channel shown in Fig. 4(A). Consider each normally closed contact from step 1. Assume that each of these contacts functions according to the statistics of the noisy symmetrical channel shown in Fig. 4(B). Make an analysis of the resulting probabilistic circuit. Each element of the resulting reliability matrix will be a function f_{JK} of A_0.

Let α_0 ces be the specified lower bound for the reliability of the allowable state transitions. Then, $P_{JK}=f_{JK}(A_0)$. The problem is to find a greatest lower bound $A_{0M}=GLB(A_0)$ so that $f_{JK}(A_0)\geq\alpha_0$ ces for all J and K.

A lower bound to A_0 is sought so as to meet the reliability specifications with as crummy a set of relays as possible.[9] A greatest lower bound is sought so that the least amount of equipment need be used, consistent with the quality of the relays available for the construction of the circuit.

By postulate 2, if $A_{0M}<0.9$, then the circuit meets the reliability specifications without the need of using additional contacts to improve the reliability. If the defining probability A_{0A} for any contacts on the relays available for the synthesis are such that $0.9\leq A_{0M}<A_{0A}$, then no additional contacts are needed either.

1	..	A_0	..	A_0^2	..
2	A_0	..	1	..	..
3	..	1	..	A_0^4	..
4	A_0^3	..	..	..	A_0^6
5	..	A_0	..	A_0^3	..

$\mathfrak{M}$

Step 3. If $0.9\leq A_{0A}<A_{0M}$, then a local improvement in the reliability for these particular contacts can be made so as to meet the specified reliability for the overall circuit. For example, let $A_{0A}=0.90$, $A_{0M1}=0.95$, and $A_{0M2}=0.97$ for a particular contact denoted $x\alpha_1$. Then make either the series-parallel transformation shown in Fig. 5(A) or the bridge transformation shown in Fig. 5(B). Fig. 6(A) shows the transformation of channels corresponding to the series-parallel transformation. This is done for the case of a normally open contact only. Fig. 6(B) shows the transformation of channels corresponding to a bridge transformation. This is done for a normally open contact only.

Thus, as far as $A_{0M1}=0.95$, the series parallel and the bridge transformations will give the required local contact reliability. However, one contact may be saved by using the series-parallel transformation.

For the case in which $A_{0M2}=0.97$, a single application of the series-parallel transformation does not give sufficient reliability. However, the bridge transformation does give sufficient reliability.

The series-parallel transformation of a symmetric channel results in a nonsymmetrical channel. However, a bridge transformation of a symmetrical channel results in another symmetrical channel. This is because a bridge network is self-dual.

An alternative means of satisfying the specified reliability conditions for the circuit is to M-truplicate in the gross. By this is meant to synthesize a number of identical relay sequential circuits. None of these quite meet the required reliability specifications for the final network. However, by coupling a sufficient number

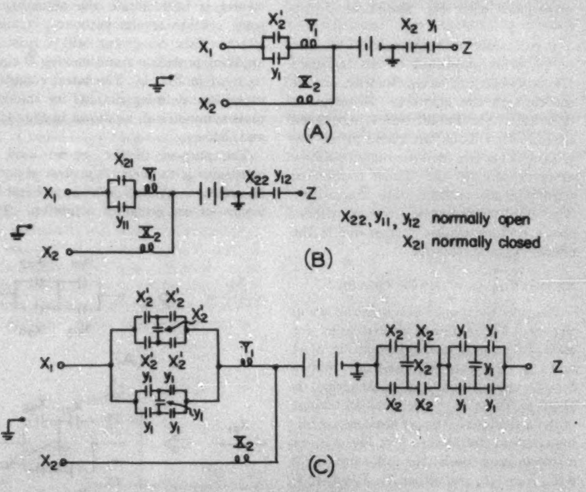

Fig. 7. Circuits and network for synthesis example

A—Corresponding classical circuit
B—Probabilistic circuit
C—Final network

of the identical circuits in the proper manner, an over-all circuit can be produced that will meet the required reliability specification.

Unlike the local improvement of reliability, the *M*-truplication of networks requires a large number of relays. If a considerable amount of local improvement is being considered, the spring load required for certain relays may exceed that which is present on the available relays. In such a case *M*-truplication in the gross gives a satisfactory solution to the synthesis problem. A majority relay, which is analogous to the majority organ described by Von Neumann, may be used as the coupling device for *M*-truplication in the gross.

Step 4. If a static hazard is present in the classical circuit of step 1 of the synthesis procedure, insert the missing prime implicant tie sets or cut sets. These inserted prime implicants will appear in the "skeleton" of the probabilistic circuit. To this extent they will be called probabilistic prime implicants or, more briefly, probimplicants. To decrease the probability of error due to the effects of static hazards, each of the probimplicants should be made as reliable as possible, consistent with the economic principle of "diminishing returns."

Let θ be the probability of error due to a malfunction in a particular probimplicant tie set or cut set. Let ϵ be the probability of error, for an allowable transition, due to the effects of a static hazard. The corrected probability of error ϵ_s, for an allowable state transition, due to the effects of a static hazard is $\epsilon_s=\theta\times\epsilon$.

SIMPLE EXAMPLE SHOWING SYNTHESIS PROCEDURES

Synthesize a relay sequential circuit with the logic property that the output line is to have the transmission function $Z=1$ if and only if the ordered set of inputs are such that $X_1, X_2=1, 1$, where X_1 became 1 before X_2. No reliability for an allowable transition of state in the resulting circuit is to be less than 3.12 ces. Assume that the available relays are defined by the channels shown in Fig. 4(A) and (B) with $A_0=0.9$.

Table IV is a flow table for the logic properties of the corresponding classical circuit. Fig. 7(A) shows a classical sequential circuit derived from inspecting the flow table according to the techniques developed by Huffman.[4] Fig. 7(B) presents the initial probabilistic sequential circuit derived from the corresponding classical circuit shown in Fig. 7(A).

The stochastic matrix for the analysis of the circuit shown in Fig. 7(B) is given in Table V. It should be noted that there is never any uncertainty in the state of the input line X_1.

Hence $-\log_2(1-A_0^4)\geq 3.12$, or $A_0=\geq 0.97$. Thus $A_{0M}=0.97$ since $A_{0A}=0.90$.

Local improvements in the individual contacts will be made. Refer to the bridge transformation shown in Fig. 5(B). This satisfies the needed local improvement in contact reliability as found by inspecting Fig. 6(B). It should be noted that the series-parallel transformation is inadequate. A final network is shown in Fig. 7(C).

Measurement of the Scattering Matrix with an Intervening Ionosphere

HENRY BRYSK
NONMEMBER AIEE

WITH THE ADVENT of radar scattering from the moon and earth satellites, it is interesting to examine the effect of the interposition of a magnetoionic medium (the ionosphere) between the observer and the scatterer upon measurements of the scattering matrix. The integrated electron density of the ionosphere is of the order of 10^{13} electrons per centimeter squared, with diurnal variations of a factor of two. A typical value of the geomagnetic field is $^1/_2$ gauss. For radar frequencies, the Faraday effect may be considered as a rotation of the plane of polarization without absorption. At 200 megacycles, the rotation is about π each way. It varies as the inverse square of the frequency. For simplicity, the discussion is restricted to backscattering; no new essential features appear in the general case. The scattering matrix of interest is, of course, that which would be present in the absence of the ionosphere, not that due to the composite system of scatterer plus ionosphere. The complication is that it can be observed only with the effect of the Faraday rotation superimposed.

With the direction of propagation as the z-axis, and let $\vec{E}^i$ be the incident field and $\vec{E}^s$ the scattered field. The scattering matrix is then described by

$$\begin{aligned} E_x^s &= S_{11}E_x^i+S_{12}E_y^i \\ E_y^s &= S_{21}E_x^i+S_{22}E_y^i \end{aligned} \qquad (1)$$

where the S_{jk} are complex numbers. By reciprocity, $S_{12}=S_{21}$. An over-all absolute phase is irrelevant. There are thus five independent real numbers that determine the S matrix: The magnitudes of S_{11}, S_{22}, and S_{12}, and the relative phases between them.

Denote the electric polarization vector of the field incident on the scatterer by $(\hat{x}\cos\theta+\hat{y}\sin\theta)$, and let $(\hat{x}\cos\alpha+\hat{y}\sin\alpha)$ be the polarization vector upon leaving the scatterer of a scattered field whose polarization on arrival at the receiver will coincide with that of the receiver. The field measured at the receiver will be

$$\begin{aligned} E^r &= E_x^s\cos\alpha+E_y^s\sin\alpha \\ &= E^i(S_{11}\cos\theta\cos\alpha+S_{22}\sin\theta\times \\ &\qquad \sin\alpha+S_{12}\sin(\theta+\alpha)) \end{aligned} \qquad (2)$$

Without the ionosphere, θ and α would be

Paper 58-532, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Great Lakes District Meeting, East Lansing, Mich., May 5–7, 1958. Manuscript submitted January 24, 1958; made available for printing May 6, 1958.

HENRY BRYSK is with the University of Michigan, Ann Arbor, Mich.

the polarization angles of the transmitter and receiver respectively, and the S-matrix would be determined by making five measurements (e.g., for the pairs of values $(\theta=0,\ \alpha=0)$, $(\theta=\pi/2,\ \alpha=\pi/2)$, and $(\theta=0,\ \alpha=\pi/2)$, one obtains $(E^r/E^t)=S_{11}$, S_{22}, and S_{12} respectively, so that if one measures the amplitude of each of the three returns and the two relative phases, the S-matrix is determined).

With the ionosphere in the way, the Faraday effect rotates the polarization vector by an angle ψ, so that if the radiation is incident with a polarization angle θ it must have started with an angle $\phi=\theta-\psi$; similarly, to receive the component of the scattered field that leaves the scatterer with polarization angle α one must receive with a polarization angle $\beta=\alpha+\psi$. Thus, if the transmitter has a polarization $(\hat{x}\cos\phi+\hat{y}\sin\phi)$ and the receiver a polarization $(\hat{x}\cos\beta+\hat{y}\sin\beta)$, the measured field will be

$$\begin{aligned}E^r=E^t[&S_{11}\cos(\phi+\psi)\cos(\beta-\psi)+\\&S_{22}\sin(\phi+\psi)\sin(\beta-\psi)+\\&S_{12}\sin(\phi+\beta)]\\=E^t[&S_{12}\sin(\phi+\beta)+(1/2)\\&(S_{11}-S_{22})\cos(\phi+\beta)+\\&(1/2)(S_{11}+S_{22})\cos(\phi-\beta)\cos\\&2\psi+(1/2)(S_{11}+S_{22})\sin(\phi-\beta)\sin 2\psi]\end{aligned}\tag{3}$$

This expression contains functions of ϕ and β which are known for a particular choice of transmitter and receiver polarizations, and the unknown quantities S_{12}, $(S_{11}-S_{22})$, $(S_{11}+S_{22})\cos 2\psi$, and $(S_{11}+S_{22})\sin 2\psi$. Four pairs of polarization angle settings are now necessary, supplying seven measurements; these suffice to determine the amplitude and phase of the unknowns just mentioned. Since the trigonometric functions are real, there is a redundancy in that the phase of the last two unknowns is the same (modulo π). It is not proper simply to discard one phase measurement on this account; the corresponding amplitude is then a quadratic expression which possesses an extraneous root (unless one of the unknowns vanishes). One can, however, use delay line circuitry to superpose the returns without loss of phase before the recording stage in such a way that the resulting linear combinations are the above unknowns; after this is done, only six quantities need be recorded for maximum information about the scattering matrix (discarding the relative sign of $\cos 2\psi$ and $\sin 2\psi$ is of no importance).

These measurements do not, however, completely determine the scattering matrix. While $\cos 2\psi$ (or $\sin 2\psi$) is real, it can be either positive or negative; unless this is known, there is an ambiguity of π in the phase of $(S_{11}+S_{22})$. Because of this ambiguity, the measurements yield two scattering matrices to choose between, only one of which is, of course, correct. (The two are identical for a matrix proportional to the unit matrix, such as occurs for the sphere). If the two solutions are denoted by superscripts a and b, and the over-all phase of one with respect to the other is fixed, they are related by

$$S_{11}^a=S_{22}^b,\ S_{22}^a=S_{11}^b,\ S_{12}^a=-S_{12}^b\tag{4}$$

The two matrices can correspond to the same object, rotated through 90 degrees about the z-axis. The dichotomy may often not matter in practice.

The complete specification of the s-matrix requires either of two additional data:

1. A determination of the Faraday rotation adequate to ascertain the sign of $\cos 2\psi$. At high enough frequencies, 2ψ will be in the first quadrant, so there is no ambiguity. At lower frequencies, simultaneous observations at two frequencies that differ slightly can pinpoint the scale of the rotation.
2. Sufficient knowledge of the physical system under observation from other sources to be able to decide which of the two scattering matrices makes sense.

Magnetic Amplifier Bibliography 1951–1956

AIEE COMMITTEE REPORT

THIS bibliography covers domestic and foreign literature for the years 1951 through 1956. The patents listed cover those issued between January 1951 and July 1956. Earlier magnetic amplifier literature is covered in the bibliography prepared by J. G. Miles.[12]

The bibliography is divided into four major subdivisions as follows:

- I. English Language Articles
- II. Foreign Language Articles
- III. Domestic Patents
- IV. Foreign Patents

Within each major subdivision, papers and patents are classified according to subject matter as follows:

- A. *Theory, Analysis, and Design*
  Papers dealing primarily with the theory of operation of magnetic amplifiers, or with the analysis and design of circuits.
- B. *Magnetic Regulation and Servo Applications*
  Applications of magnetic amplifiers in the control of voltage, current, speed, temperature, frequency, position, etc.
- C. *Magnetic Frequency Conversion*
  Sub- and ultraharmonic generators and magnetic frequency converters.
- D. *Operational and Instrument Magnetic Amplifiers*
  Metering and operational magnetic amplifiers and applications in analog computation. Magnetic modulators.
- E. *Static Magnetic Switching Applications*
  Digital computer applications and discrete step output magnetic amplifiers. Bistate magnetic amplifiers.
- F. *Transistor–Magnetic Device Combinations*
  All applications where transistors are used in conjunction with magnetic devices to provide new capabilities.
- G. *Magnetism and Magnetic Materials*
  Magnetic phenomena and the properties of magnetic amplifier materials.
- H. *Measurements and Testing*
  Techniques for the measurement of magnetic properties, core matching, and grading. Methods for measuring magnetic amplifier performance.
- J. *Associated Devices*
  Components used in conjunction with saturable reactors in magnetic amplifier circuitry. Devices generally associated with magnetic amplifier technique such as rectifiers, reference elements, etc.
- K. *Ferroresonance and Its Applications*
  The phenomenon of ferroresonance and its applications in regulation and harmonic frequency generation.
- L. *Manufacturing Techniques, Environmental Effects, and Reliability*
  Manufacturing and packaging techniques utilized to obtain a product reliable over a wide range of environmental conditions. The effects of radiation and temperature on magnetic amplifier performance.

Each subject heading is further subdivided into years. For each year, the papers under a given subject classification are listed alphabetically by author, except for patents which are listed in order of increasing patent numbers.

A list of abbreviations of the journals referred to in the bibliography and a list of general references on magnetic amplifiers follows.

Paper 58-996, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the Joint AIEE-IRE Nonlinear Magnetics and Magnetic Amplifiers Conference, Los Angeles, Calif., August 6–8, 1958. Manuscript submitted April 3, 1958; made available for printing May 1, 1958.

The members of the Bibliography Working Group of the Applications Subcommittee of the AIEE Magnetic Amplifiers Committee are B. J. ALEXANDER, *chairman;* V. B. Boros, W. A. Geyger, R. E. Morgan, and R. A. Raber. Other members of the Applications Subcommittee made significant contributions to this bibliography. Special mention is due L. W. Buechler for his initial work which provided the basis for this bibliography, and W. G. Evans, David Katz, H. M. Ogle, H. F. Storm, and T. G. Wilson, all of whom contributed lists of references.

List of Journals and Their Abbreviations

ACEC Rev. (Belgium)	*ACEC Revue.* Ateliers de Constructions Électriques de Charleroi, Rue Vital Francoise, Marcinelle-Charleroi, Belgium
AEG Mitt. (Berlin)	*AEG Mitteilungen.* Hohenzollerndamm 150, Berlin-Grunewald, Germany
Aeron. Engg. Rev.	*Aeronautical Engineering Review.* Institute of the Aeronautical Sciences, Inc., 2 E. 64th Street, New York 21, N.Y.
AIEE Trans.	*Transactions,* American Institute of Electrical Engineers, 33 W. 39th Street, New York 18, N.Y.
Allis-Chalmers Elec. Rev.	*Allis-Chalmers Electrical Review.* Allis-Chalmers, Milwaukee 1, Wis.
Appl. Sci. Research (Hague)	*Applied Scientific Research.* Martinus Nijhoff, The Hague, Netherlands
Arch. Elektr. Übertr. (Stuttgart)	*Archiv der Elektrischen Übertragung.* S. Hirzel Verlag, Birkenwaldstrasse 185, Stuttgart, Germany
ASEA J.	*ASEA Journal.* ASEA Electric Ltd., Fulbourne Road, London, E. 17; Allmänna Svenska Elektriska AB, Vasteras, Sweden
ATM (Munich)	*Archiv für Technisches Messen.* Leibniz Verlag, Lotzbeckstr. 2b, Munich, Germany
Australian J. Appl. Science	*Australian Journal of Applied Science.* Commonwealth Scientific and Industrial Research Organization, 314 Albert Street, East Melbourne, C2, Australia
Automation and Remote Control (USSR)	*Avtomatika i Telemekhanika.* Institute of Automatics and Telemechanics, Moscow Center, Mal. Kharitonievsky, Per 4, Moscow, USSR
Blast F. & Steel Pl.	*Blast Furnace and Steel Plant.* Steel Publications, Inc., 330 Grant Street, Pittsburgh 30, Pa.
Brit. Commun. & Electronics	*British Communications and Electronics.* Drury House, Russell Street, Drury Lane, London, W.C. 2, England.
BSTJ	*The Bell System Technical Journal.* American Telephone and Telegraph Company, 195 Broadway, New York 7, N.Y.
Bull. de l'Association Suisse Electr.	*Bulletin de l'Association Suisse des Electriciens.* Secretariat General de l'A.S.E. et de l'U.C.S. Seefeldstrasse 301, Zurich 8, Switzerland
Bull. Int. Rly. Cong. Ass.	*Monthly Bulletin of the International Railway Congress Association* (English Edition). 19 rue de Beau-Site, Brussels, Belgium
Bull. Sci. Ass. Ing. Élect. Montefiore	*Bulletin Scientifique de l'Association des Ingénieurs Électriciens Sortis, de l'Institut Électrotechnique Montefiore.* 31 Rue Saint Gilles, Liege, Belgium

Bull. Soc. Belge Électr.	*Bulletin Société, Belge des Électriciens.* 8 rue Sabatier, Marcinelle, Belgium
Bull. Soc. Franc. Électr.	*Bulletin de la Société Francaise des Électriciens.* 8-14 Avenue Pierre Larousse, Malakoff, Seine, France
Cont. Engg.	*Control Engineering.* McGraw-Hill Book Company, Inc., 330 W. 42nd Street, New York 36, N.Y.
Conv. Rec. IRE.	*Convention Record,* Institute of Radio Engineers, 1 E. 79th Street, New York 21, N.Y.
Direct Current	*Direct Current.* Garraway Ltd., 11A Kensington Church Street, London, W. 8, England
Dtsch. Electrotechnik	*Deutsche Electrotechnik.* Verlag Technik, Unter den Linden 12, Berlin, N.W. 7, Germany
Elec. Engg.	*Electrical Engineering.* American Institute of Electrical Engineers, 33 West 39th Street, New York, N.Y.

1951

658. Voltage Doubler Magnetic Amplifier, R. E. Morgan. *No. 2,552,203*, Apr. 2, 1948–May 8, 1951.

659. **Magnetic Amplifier, P. Gachet, P. J. Augier de Montgremier.** *No. 2,552,952*, July 15, 1948–May 15, 1951.

660. **Magnetic Amplifier Control System, R. E. Morgan.** *No. 2,554,203*, Nov. 10, 1949–May 22, 1951.

661. **Magnetic Amplifier, G. Hepp.** *No. 2,556,083*, July 8, 1946–June 5, 1951.

662. **Means for Reinforcing Electric Currents by Direct-Current Saturated Inductances, U. Lamm.** *No. 2,562,047*, Oct. 21, 1947–July 24, 1951.

663. **Three Phase Control System Employing Saturable Reactors, R. E. Morgan.** *No. 2,567,725*, Oct. 31, 1950–Sept. 11, 1951.

664. **Means for Reproducing a Direct Current, H. Forssel.** *No. 2,573,255*, Dec. 24, 1947–Oct. 30, 1951.

665. **Magnetic Amplifier, E. G. Downie.** *No. 2,578,405*, Feb. 28, 1950–Dec. 11, 1951.

1952

666. **Electromagnetic System, A. S. FitzGerald.** *No. 2,584,856*, Dec. 31, 1946–Feb. 5, 1952.

667. **Spare Connected Polyphase Transductor, H. M. Sörensen.** *No. 2,599,137*, Apr. 20, 1949–June 3, 1952.

668. **Transductor, J. W. Trindle.** *No. 2,603,768*, Apr. 20, 1950–July 15, 1952.

669. **Saturable Reactor Apparatus, H. M. Ogle.** *No. 2,617,090*, June 17, 1950–Nov. 4, 1952.

670. **Direct Current Control System, M. Bracutt.** *No. 2,622,239*, Mar. 18, 1950–Dec. 16, 1952.

1953

671. **Magnetic Amplifier Circuits for Applying Reversible Direct-Current Voltage to Inductive Loads, W. F. Eames, W. H. Esselman.** *No. 2,629,847*, Aug. 25, 1950–Feb. 24, 1953.

672. **Magnetic Amplifier System, H. F. McKenney, H. Kaplan.** *No. 2,636,150*, Mar. 30, 1951–Apr. 21, 1953.

673. **Spare Connected Polyphase Transductor, H. M. Sörensen, H. Forssel.** *No. 2,640,963*, June 14, 1949–June 2, 1953.

674. **Separate Magnetization of Magnetic Amplifiers, R. A. Ramey.** *No. 2,644,129*, Dec. 27, 1950–June 30, 1953.

675. **Electromagnetic Audio Amplifier, W. C. Kluz.** *No. 2,657,281*, Feb. 15, 1950–Oct. 27, 1953.

676. **Saturable Core Transformer System, A. V. Hemingway, P. D. Atkinson.** *No. 2,661,453*, Aug. 3, 1949–Dec. 1, 1953.

1954

677. **Magnetic Amplifier Circuit, R. E. Morgan.** *No. 2,675,518*, Feb. 28, 1951–Apr. 13, 1954.

678. **Reversible Inductive Load Controlled Magnetic Amplifiers, J. T. Carleton.** *No. 2,677,084*, Apr. 9, 1952–Apr. 27, 1954.

679. **Magnetic Amplifier, F. J. Rau.** *No. 2,677,099*, Mar. 29, 1952–Apr. 27, 1954.

680. **Saturable Transformer Device, A. Bennett.** *No. 2,678,419*, Sept. 30, 1946–May 11, 1954.

681. **Magnetic Amplifier Circuit, R. Cohen, H. F. Storm.** *No. 2,682,632*, May 20, 1949–June 29, 1954.

682. **Power Transmission, F. G. Logan.** *No. 2,683,853*, Nov. 29, 1951–July 13, 1954.

683. **Magnetic Amplifier System, D. T. Kadushin, H. Kaplan.** *No. 2,688,723*, Sept. 16, 1949–Sept. 7, 1954.

684. **Magnetic Amplifier, W. H. Newell.** *No. 2,688,724*, Apr. 27, 1951–Sept. 7, 1954.

685. **Saturable Reactor Device, F. G. Logan.** *No. 2,689,328*, Dec. 1, 1950–Sept. 14, 1954.

686. **Magnetic Amplifier System, J. Stone.** *No. 2,697,813*, Apr. 12, 1951–Dec. 21, 1954.

1955

687. **Magnetic Amplifier System, H. F. Storm.** *No. 2,704.823*, Feb. 29, 1952–Mar. 22, 1955.

688. **Electromagnetic Audio Amplifiers, F. G. Logan.** *No. 2,710,313*, Oct. 12, 1948–June 7, 1955.

689. **Electric Motor Control Circuit Using Saturable Reactors, R. E. Morgan.** *No. 2,715,203*, June 17, 1950–Aug. 9, 1955.

690. **Magnetic Amplifier with High Gain and Rapid Response, R. A. Ramey.** *No. 2,719,885*, July 20, 1951–Oct. 4, 1955.

691. **Magnetic Amplifier for Power Transmission, S. Steinitz.** *No. 2,723,373*, Apr. 25, 1950–Nov. 8, 1955.

1956

692. **Magnetic Amplifier, F. H. Beisey.** *No. 2,730,574*, Aug. 22, 1951–Jan. 10, 1956.

693. **Magnetic Amplifiers, J. A. Crawford.** *No. 2,731,521*, Aug. 12, 1952–Jan. 17, 1956.

694. **Rapid Response Self-Saturating Magnetic Amplifier, B. D. Bedford.** *No. 2,733,306*, July 29, 1952–Jan. 31, 1956.

695. **Stabilized Full-Wave Self-Saturating Magnetic Amplifier, H. M. Ogle.** *No. 2,733,307*, Apr. 23, 1953–Jan. 31, 1956.

696. **Magnetic Amplifier, A. W. Rechten, B. M. Bellman.** *No. 2,733,388*, Feb. 18, 1952–Jan. 31, 1956.

697. **Self-Excited Transductors, A. Arvidsson.** *No. 2,733,403*, June 16, 1952–Jan. 31, 1956.

698. **Magnetic Amplifier with Half-Wave Phase-Reversal Type Output, C. W. Lufcy, A. E. Schmid, Jr.** *No. 2,734,165*, June 30, 1952–Feb. 7, 1956.

699. **Magnetic Amplifier Circuit, M. B. Zucchino.** *No. 2,745,056*, May 4, 1953–May 8, 1956.

700. **Magnetic Amplifier, S. B. Cohen, J. Bentkowsky.** *No. 2,745,908*, Jan. 10, 1951–May 15, 1956.

701. **Magnetic Amplifier, K. M. Hanson.** *No. 2,752,429*, Jan. 7, 1952–June 26, 1956.

702. **Magnetic Amplifiers, F. A. Baker.** *No. 2,752,560*, Apr. 18, 1955–June 26, 1956.

703. **Magnetic Amplifier, C. J. Creveling.** *No. 2,753,518*, June 1, 1953–July 3, 1956.

704. **Half-Wave Bridge Magnetic Amplifier, E. T. Hooper, Jr.** *No. 2,754,473*, Apr. 9, 1953–July 10, 1956.

705. **Arrangement for Producing Full-Wave Output from Half-Wave Magnetic Amplifiers, P. W. Barnhart.** *No. 2,754,474*, Apr. 13, 1955–July 10, 1956.

B. Magnetic Regulation and Servo Applications

1951

706. **Follow-Up Apparatus, G. N. Burkhart, Jr.** *No. 2,537,027*, Feb. 8, 1947–Jan. 9, 1951.

707. **Voltage Regulator, M. Ker.** *No. 2,541,820*, Nov. 12, 1946–Feb. 13, 1951.

708. **Saturable Core Reactor, B. D. Bedford.** *No. 2,547,615*, Oct. 26, 1948–Apr. 3, 1951.

709. **Magnetic Amplifier, R. W. Olson.** *No. 2,548,049*, July 10, 1948–Apr. 10, 1951.

710. **Heat-Regulating System, A. S. FitzGerald.** *No. 2,554,945*, July 11, 1947–May 29, 1951.

711. **Motor Control System, H. M. Ogle.** *No. 2,555,992*, Feb. 3, 1950–June 5, 1951.

712. **Electric Controlling Apparatus, F. G. Logan.** *No. 2,558,572*, June 9, 1945–June 26, 1951.

713. **Servo System with Saturable Core Component, J. P. Palmer.*** *No. 2,559,513*, Dec. 28, 1948–July 3, 1951.

714. **Reversing Magnetic Amplifier Control System, W. L. O. Graves.** *No. 2,571,708*, May 21, 1949–Oct. 16, 1951.

715. **Saturable Reactor Impedance Relay, F. Dahlgren.** *No. 2,573,249*, Aug. 23, 1947–Oct. 30, 1951.

1952

716. **Electric Controlling Apparatus, F. G. Logan.** *No. 2,585,332*, Feb. 10, 1948–Feb. 12, 1952.

717. **Rectifier Connection, H. Öfverholm, H. Forssell.** *No. 2,588,155*, Sept. 10, 1947–Mar. 4, 1952.

718. **Magnetic Amplifier Relay Circuits, W. F. Horton.** *No. 2,594,022*, Aug. 5, 1950–Apr. 22, 1952.

719. **Regulator with Saturable Core, S. E. Hedström.** *No. 2,596,685*, Sept. 17, 1947–May 13, 1952.

720. **Voltage Regulator, H. M. Ogle.** *No. 2,615,155*, Oct. 21, 1952.

1953

721. **Saturable Core Reactor System, F. Landau, J. E. Carlsson, S. E. Hedström.** *No. 2,625,677*, Aug. 21, 1947–Jan. 13, 1953.

722. **Regulating System, E. L. Harder, S. L. Bradley.** *No. 2,629,853*, Dec. 22, 1951–Feb. 24, 1953.

723. **Voltage Regulator, D. H. Ransom, H. M. Miller.** *No. 2,631,268*, Mar. 13, 1951–Mar. 10, 1953.

724. **Self-Biasing Magnetic Amplifier, D. J. Sikorra.** *No. 2,632,145*, Jan. 20, 1951–Mar. 17, 1953.

725. **Voltage Regulating Device, Y. A. Rocard.** *No. 2,633,562*, Oct. 29, 1949–Mar. 31, 1953.

726. **Electrical Control Circuit, P. Glass.** *No. 2,634,395*, July 12, 1945–Apr. 7, 1953.

727. **Regulating System, S. L. Bradley.** *No. 2,644,127*, Dec. 22, 1951–June 30, 1953.

728. **Stabilizer for Alternating Current Power Transmission Systems, E. F. W. Alexanderson, R. W. Kuenning.** *No. 2,644,898*, Feb. 28, 1951–July 7, 1953.

729. **Voltage Regulators, F. R. Milsom.** *No. 2,651,020*, July 23, 1951–Sept. 1, 1953.

1954

730. **Magnetic Amplifier Motor Control Device, F. S. Malick.** *No. 2,675,513*, June 4, 1953–Apr. 13, 1954.

731. **Magnetic Amplifier for Controlling the Voltages Applied to Motor Armatures, F. S. Malick.** *No. 2,677,088*, Aug. 9, 1952–Apr. 27, 1954.

732. **Regulator System for Generators, J. T. Carleton.** *No. 2,677,097*, Feb. 5, 1953–Apr. 27, 1954.

733. **Two-Phase Induction Motor Magnetic Amplifier with Direct-Current Braking, W. A. Geyger.** *No. 2,677,796*, Mar. 11, 1952–May 4, 1954.

734. **Inverter Frequency Regulator, H. H. Woerdemann.** *No. 2,682,633*, Apr. 5, 1952–June 29, 1954.

735. **Magnetic Servo Amplifier with Direct-Current Damping, W. A. Geyger.** *No. 2,683,843*, July 20, 1953–July 13, 1954.

736. **Bridge Control Circuits, W. H. Ingersoll.** *No. 2,691,130*, Aug. 11, 1952–Oct. 5, 1954.

737. **Saturable Reactor Using Permanent Magnets, W. J. Brown.** *No. 2,696,583*, Aug. 17, 1949–Dec. 7, 1954.

738. **Saturable Reactor Motor Control Systems, W. J. Brown.** *No. 2,697,194*, Aug. 17, 1949–Dec. 14, 1954.

739. **Control System Using Multiple Winding Saturable Reactors, W. J. Brown.** *No. 2,697,197*, Aug. 17, 1949–Dec. 14, 1954.

1955

740. **Voltage Regulator Employing Saturable Reactor, R. E. Morgan.** *No. 2,699,525*, Feb. 8, 1951–Jan. 11, 1955.

741. **Magnetic Voltage Regulator, H. H. Woerdemann.** *No. 2,700,128*, May 5, 1952–Jan. 18, 1955.

742. **Motor Control Systems, N. S. Wells.** *No. 2,709,774*, Nov. 13, 1952–May 31, 1955.

743. **Alternating-Current Motor, E. F. W. Alexanderson.** *No. 2,711,502*, July 21, 1954–June 21, 1955.

744. **Alternating Current Motor Control,**

III: Domestic Patents

B. Magnetic Regulation and Servo Applications

1955 (cont'd.)

G. E. Mathias, W. T. Hunt. *No. 2,712,105*, Nov. 19, 1952–June 28, 1955.

745. Electric Regulation by Controlled Reversible Motor, **W. Few.** *No. 2,713,137*, Oct. 31, 1949–July 12, 1955.

746. Regulating System with Exciter Field Winding in Series with Alternator Field Winding, **W. L. Ringland.** *No. 2,715,205*, May 18, 1953–Aug. 9, 1955.

747. Magnetic Servo Amplifier, **W. A. Geyger.** *No. 2,717,346*, Apr. 2, 1953–Sept. 6, 1955.

748. Amplifier Limit Circuit, **V. J. Louden.** *No. 2,717,355*, Aug. 18, 1952–Sept. 6, 1955.

749. Alternating Current Motor Control Systems for Printing Presses or the Like, **H. R. Behr, E. C. Rhyne.** *No. 2,719,255*, Oct. 6, 1951–Sept. 27, 1955.

750. Voltage-Controlled A C Generator System, **D. G. Scorgie.** *No. 2,719,260*, May 29, 1953–Sept. 27, 1955.

751. Temperature Control System for Electric Heating Elements, **R. E. Morgan.** *No. 2,720,579*, Apr. 3, 1952–Oct. 11, 1955.

752. Motor Control Apparatus, **P. Siskind.** *No. 2,721,298*, Sept. 25, 1951–Oct. 18, 1955.

753. Voltage Regulators, **N. Silver.** *No. 2,721,303*, Nov. 22, 1954–Oct. 18, 1955.

754. Voltage Regulator, **N. Silver, D. W. Tanner.** *No. 2,721,304*, June 21, 1954–Oct. 18, 1955.

755. Current Limit Motor Control System, **W. T. Hunt, Jr.** *No. 2,722,642*, Jan. 30, 1953–Nov. 1, 1955.

756. Control System for Alternating Current Motors, **E. C. Rhyne, Jr.** *No. 2,722,643*, Oct. 6, 1951–Nov. 1, 1955.

757. Alternating-Current Motor Control Systems, **E. C. Rhyne, H. R. Behr.** *No. 2,722,646*, Oct. 6, 1951–Nov. 1, 1955.

758. Regulating System Utilizing a Saturable Reactor Having Negative Feedback, **D. J. Sikorra.** *No. 2,722,654*, Dec. 11, 1950–Nov. 1, 1955.

759. Line Voltage Regulator, **F. W. Anderson.** *No. 2,722,655*, Apr. 10, 1953–Nov. 1, 1955.

760. Stabilizing Circuit for Alternating-Current Generator, **H. F. Storm.** *No. 2,724,797*, Feb. 1, 1951–Nov. 22, 1955.

761. Frequency-Selective System, **H. B. Rex.** *No. 2,724,807*, Feb. 16, 1950–Nov. 22, 1955.

762. Magnetic Amplifier Electrical Position Control System, **F. S. Malick, C. L. Mershon.** *No. 2,725,519*, Mar. 31, 1952–Nov. 29, 1955.

763. Electrical Error Detector, **W. H. Woodworth.** *No. 2,725,520*, Nov. 4, 1954–Nov. 29, 1955.

764. Differential Coupling Circuit for Multi-Stage Half-Wave Magnetic Servo Amplifiers, **W. A. Geyger.** *No. 2,725,521*, Jan. 26, 1955–Nov. 29, 1955.

765. Variable Frequency Power Control Systems for A-C Motors, **H. M. Ogle.** *No. 2,727,199*, May 18, 1953–Dec. 13, 1955.

766. Motor Control System, **M. A. Edwards.** *No. 2,727,201*, July 29, 1952–Dec. 13, 1955.

767. Regulator Systems, **G. H. Stearley.** *No. 2,728,044*, Aug. 16, 1954–Dec. 20, 1955.

1956

768. Magnetic Amplifier Circuit for Motor, **E. L. Gardner.** *No. 2,729,777*, Nov. 12, 1954–Jan. 3, 1956.

769. Motor Control System Utilizing Magnetic Amplifiers, **F. R. Milsom.** *No. 2,729,779*, Dec. 12, 1950–Jan. 3, 1956.

770. Electric Control Apparatus, **A. H. B. Walker, K. G. King.** *No. 2,732,505*, Aug. 26, 1953–Jan. 24, 1956.

771. Thermal Time-Constant Circuit, **H. M. Ogle.** *No. 2,733,404*, Nov. 27, 1951–Jan. 31, 1956.

772. Three Phase Motor System, **H. F. McKenney, L. H. Rowley.** *No. 2,734,157*, Jan. 15, 1953–Feb. 7, 1956.

773. Magnetic Amplifier Regulated Current Limit Control for Ward Leonard Systems, **C. H. Storey, Jr., W. T. Hunt, Jr.** *No. 2,735,053*, Feb. 27, 1953–Feb. 14, 1956.

774. Magnetic Amplifier Motor Speed Control, **F. S. Malick.** *No. 2,735,060*, Aug. 16, 1952–Feb. 14, 1956.

775. Control System Using Two Saturable Reactors in a Constant Current Circuit, **R. L. Peterson.** *No. 2,740,933*, Jan. 26, 1953–Apr. 3, 1956.

776. Voltage Stabilizer and Reference Circuit Therefor, **R. E. Anderson.** *No. 2,740,936*, Dec. 30, 1953–Apr. 3, 1956.

777. Voltage Reference Circuit, **J. T. Carleton.** *No. 2,743,152*, Mar. 26, 1953–Apr. 24, 1956.

778. Motor Control by Magnetic Servo Amplifier, **W. A. Geyger.** *No. 2,743,407*, Nov. 30, 1953–Apr. 24, 1956.

779. Load and Control Current Feedback Magnetic Amplifier, **H. H. Woerdemann.** *No. 2,745,055*, Dec. 19, 1951–May 8, 1956.

780. Motor Control System, **R. S. Crenshaw, Jr.** *No. 2,750,549*, June 1, 1953–June 12, 1956.

781. Magnetic Type Temperature Controller, **W. T. Hage.** *No. 2,752,473*, June 26, 1952–June 26, 1956.

782. Control System Utilizing Magnetic Amplifier for Reference Voltage, **A. C. Halter.** *No. 2,752,545*, Nov. 18, 1953–June 26, 1956.

783. Magnetic Amplifier Motor Control, **E. F. W Alexanderson.** *No. 2,752,549*, July 27, 1953–June 26, 1956.

784. Adjustable Voltage Drives for Electric Motor, **E. Pell.** *No. 2,753,504*, Nov 22, 1954–July 3, 1956.

785. Combination Control and Reference Circuit for a Magnetic Amplifier, **E. T. Hooper, Jr.** *No. 2,753,517*, Mar. 27, 1953–July 3, 1956.

C. Magnetic Frequency Conversion

1952

786. Harmonic Generator, **C. A. Lovell, D. B. Parkinson.** *No. 2,580,446*, Dec. 31, 1948–Jan. 1, 1952.

787. Frequency Generator Employing a Magnetic Double Cross Valve, **H. J. McCreary.** *No. 2,611,119*, Sept. 15, 1950–Sept. 16, 1952.

788. Magnetic Cross Valve Having Self Starting Characteristics, **H. J. McCreary.** *No. 2,611,120*, June 21, 1950–Sept. 16, 1952.

789. Device for the Polyphase Transformation of the Frequency of Three-phase Circuits, **U. Corbino.** *No. 2,616,070*, Dec. 8, 1949–Oct. 28, 1952.

1953

790. Electrical Converter, **A. W. La Marche.** *No. 2,651,018*, May 8, 1950–Sept. 1, 1953.

1954

791. Frequency Multiplier, **W. Krämer.** *No. 2,666,178*, Oct. 7, 1950–Jan. 12, 1954.

1955

792. Magnetic Cross Valve Circuits, **H. J. McCreary.** *No. 2,703,388*, May 16, 1950–Mar. 1, 1955.

D. Operational and Instrument Magnetic Amplifiers

1954

843. Instrument Transformer for Measurement of Very High D-C Voltages, W. Krämer. *German No. 905,407*, Oct. 18, 1941–Jan. 14, 1954.

844. D-C Instrument Transformer, W. Krämer. *German No. 907,673*, Oct. 14, 1939–Feb. 18, 1954.

845. D-C Instrument Transformer, W. Krämer. *German No. 901,454*, Jan. 15, 1938–Mar. 25, 1954.

846. D-C Instrument Transformer with Negative-Feedback Ampere-turns, W. Blankenburg. *German No. 913,198*, Mar. 6, 1943–June 10, 1954.

1955

847. Arrangement for Measuring Direct Currents and D-C Voltages, W. A. Geyger. *German No. 932,508*, Dec. 15, 1938–Sept. 1, 1955.

848. Arrangement for Measuring Small D-C Quantities by Means of an Alternating-Current Differential-Type Circuit, W. A. Geyger. *German No. 935,141*, Nov. 12, 1939–Nov. 10, 1955.

1956

849. Arrangement for Reducing the Response Time of the Electrical Measuring Instrument in Self-Balancing Potentiometer Devices, W. A. Geyger. *German No. 940,177*, Dec. 13, 1939–Mar. 15, 1956.

The Analysis of Redundancy Networks

FRED MOSKOWITZ
NONMEMBER AIEE

ELECTRICAL and electronic engineers are familiar with the impedance concepts of electric networks. In such networks the parameters of interest are impedances, admittances, currents, voltages, and other related attributes. As early as 1932, Foster[1] in a classic paper recognized that the electric network is a special class of a more general class of oriented graphs and geometrical circuits. More recently, Shannon,[2] Von Neumann,[3] Mason,[4,5] and others have shown that network and circuit concepts can be profitably applied to a large variety of problems, for example, the design and the analysis of switching circuits, the solution of problems in probability, the analysis of functional relationships, etc.

It is the purpose of this paper to investigate some of the properties of network which can be used to represent reliability relationships in complex equipments containing redundant elements, communication nets having many alternative communication paths, and operating systems containing alternative subsystems. In such problems each element is characterized by a single statistical parameter. A single element can be represented as a branch of a network between an input node and an output node.

If Fig. 1 represents an element of a system or an equipment, then p is the probability that the element will not fail. How is this parameter measured or determined? In the case where the element is assumed to be part of an equipment or a

Paper 58-538, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted February 10, 1958; made available for printing April 30, 1958.

Mr. Fred Moskowitz is with the Rome Air Development Center, Griffiss Air Force Base, N. Y.

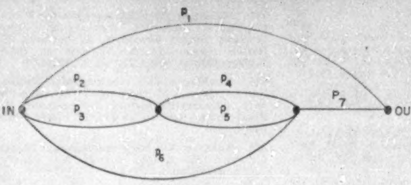

Fig. 2. A series-parallel network

system, it must be assumed that that particular element is a typical sample of a population of "identical" elements, i.e., if the average value of the population parameter is p, then individuals sampled from the population may be expected to exhibit the parameter p, except for chance variations.

If these assumptions are satisfied, the following test may be performed: Take a large sample N and subject it to a life test under specified environmental conditions. After a time t, observe the number S, that survive. The ratio of an average S to N is the survival probability p to time t.

The physical significance of the symbols in Fig. 1 in this case are: X_{in} is the number of items with survival probability p initially available, and X_{out} is the number of items expected to remain after time t. Fig. 1 then represents the linear relationship

$$X_{out}=pX_{in} \tag{1}$$

The central problem of analysis to be considered in this paper is the following: Given a system, equipmemt, or communication net, made up of a number of individual elements, each element being characterized by a reliability factor as defined by Fig. 1, find the over-all reliability factor. It will be assumed in this paper that each reliability factor is independent of all others.

In dealing with redundancy and reliability it is necessary to investigate as to how a given physical situation may be translated into an equivalent probabilistic network and then to consider various methods of solving such networks.

The advantage of the network approach in the solution of reliability and redundancy problems is the same as the advantage gained in the use of networks in the solution of electric circuit problems.

A large complex problem which cannot be solved all at once may be reduced to a series of smaller problems, each of which is amenable to solution from elementary considerations.

Canonical Form for Redundancy Networks

In principle all redundancy networks, no matter how large or complex, may be solved by summing all the possible probabilities favorable to the event that "the networks will not fail." Each additional element in the network doubles the total number of possible combinations; thus for 10 elements more than a thousand terms must be considered, while for 20 elements, the number of terms is greater than one million. This limits the simple exhaustive procedure to very small networks in practice.

In general, for n elements, the canonical equation can be written as:

$$\begin{aligned} &p_1p_2\ldots p_n+p_1q_2\ldots p_n+p_1p_2\ldots q_n+ \\ &\qquad q_1p_2\ldots p_n+\ldots+q_1q_2\ldots q_n=1 \end{aligned} \tag{2}$$

The techniques to be described permit the breaking down of complex networks into a series of elementary ones and, conversely, to compose complex networks by proper combination of simpler ones. Therefore it will be necessary to have recourse to the canonical formulation only for formal proofs of theorems.

Elementary Networks

All redundancy networks may be broken down into or built up from combinations of the following three basic elementary types: series networks, parallel networks, or bridge networks.

SERIES NETWORK

All elements in series can be replaced by a single element having a reliability factor equal to the product of the reliability factors of the elements being replaced.

For elements in series, then

$$P_{series}=\prod_{i=1}^{n} p_i=p_1p_2\ldots p_n \tag{3}$$

For the case where all the elements have identical values

$$P_{series}=p^n \tag{4}$$

PARALLEL NETWORK

A network consisting of all elements in parallel can be replaced by a single element having a reliability factor equal to one, minus the product of the unreliability factors of the elements replaced. Therefore

$$P_{parallel}=1-\prod_{i=1}^{n} q_i=1-(q_1q_2\ldots q_n) \tag{5}$$

where

$$q_i=1-p_i$$

For the case where all elements have identical reliabilities

$$P_{parallel}=1-q^n \tag{6}$$

A convenient shorthand notation to use for parallel networks is the "and/or" operator, designated in this paper by a cross, X. Thus p_1 in parallel with p_2 may be written as $p_1 \mathrm{X} p_2$ and read as "either p_1 and/or p_2." For n elements in parallel equations 5 and 6 may be written as follows

$$\begin{aligned} P_{parallel}&=p_1\mathrm{X}p_2\mathrm{X}p_3\mathrm{X}\ldots\mathrm{X}p_n \\ &=\mathop{\mathrm{X}}_{i=1}^{n} p_i=1-\prod_{i=1}^{n} q_i \end{aligned} \tag{7}$$

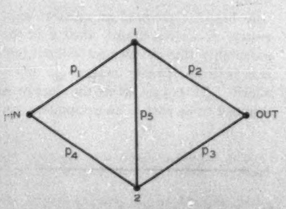

Fig. 3. A simple bridge network

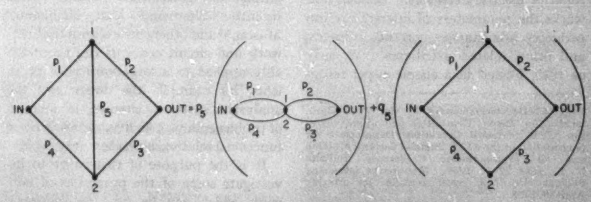

Fig. 4. The factoring theorem applied to a bridge

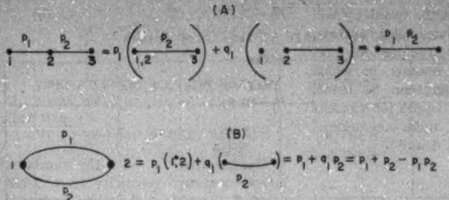

Fig. 5. Application of factoring theorem. A—Series circuit. B—Parallel circuit

SERIES-PARALLEL NETWORK

By means of two operators, the dot representing elements in series and the cross representing elements in parallel, it is possible to write the network function of any series-parallel network by inspection. The network function can then be transformed into conventional algebraic form by manipulating the function in accordance with simple algebraic rules of transformation. As an example consider the following series-parallel network consisting of seven elements. To solve the network of Fig. 2 by the canonical method would require examining 2 or 128 combinations. The network function, however, may be written directly from the diagram by applying the series-parallel principles just outlined.

The network function is

$$H(p_1,p_2,\ldots p_7)=p_1\mathrm{X}\{p_7\cdot[p_6\mathrm{X}(p_2\mathrm{X}p_3)\cdot(p_4\mathrm{X}p_5)]\} \quad (8)$$

In essence the network is solved by writing equation 8. If numerical values are assigned to the network elements, then a numerical value can be found for H by transforming equation 8 into the algebraic form in which only the operations of addition, subtraction, and multiplication exist. The transformation rules for the dot and cross operators are*

Dot operator: $x\cdot y=xy$
Cross operator: $x\mathrm{X}y=x+y-xy$

with these transformation rules, equation 8 can be expanded into standard algebraic form:

$$\begin{aligned}H=p_1+p_7[p_6+(p_2+p_3-p_2p_3)(p_4+p_5-\\ p_4p_5)-p_6(p_2+p_3-p_2p_3)(p_4+p_5-p_4p_5)]\\ -p_1p_7[p_6+(p_2+p_3-p_2p_3)(p_4+p_5-p_4p_5)-\\ p_6(p_2+p_3-p_2p_3)(p_4+p_5-p_4p_5)]\end{aligned} \quad (9)$$

Since in equation 9 conventional algebraic operations are involved, a numerical value for the over-all network reliability H may be obtained by substituting numerical values for the element reliabilities p_1, p_2, etc. Or if the value for H and values for all but one of the element reliabilities are given, it is possible to solve for the unknown element reliability.

BRIDGED NETWORKS: THE FACTORING THEOREM

Although the series-parallel technique is applicable to a large class of redundancy networks, it breaks down for networks containing cross-connected or bridging elements, such as p_5 in Fig. 3.

Bridge-type networks can be solved by applying the factoring theorem of Boolean algebra. A formal proof of this theorem is given in the Appendix.

For redundancy networks the theorem may be stated in the following form: A redundancy network function is equal to the reliability factor of any one single element of the network times the resulting network function with the terminals of the element short-circuited, plus the unreliability factor of the element times the resulting network function with the terminals of the element open-circuited.

By applying the factoring theorem to Fig. 3 the bridging element p can be removed and the bridge network transformed into the sum of two series-parallel networks which can be solved by the methods of the previous section; see Fig. 4.

The factoring theorem need not be limited to bridge-type networks, although it has been found to be most useful in reducing bridge networks to series-parallel ones by removing internal connections. As Fig. 5 shows, the elementary network transformations previously derived from other considerations may be obtained by applying the theorem to a simple series and a simple parallel circuit.

The factoring theorem does for redundancy network theory what Norton's and Thevenins's theorems do for electrical circuit theory. In each case, a complex network which is difficult to analyze as a whole can be reduced to several simpler networks. A complex problem is thus made amenable to piecemeal solution. Table I summarizes the information for elementary networks.

Problem of a Simple Bridge Redundancy Network

Consider the following hypothetical physical situation: There are two search radars, remotely located, but with overlapping search coverage patterns. Each radar is capable of a delayed video output which is relayed over individual com-

TABLE I

ELEMENTARY NETWORK TRANSFORMATIONS

	TYPE	NETWORK	EQUIVALENCE
1.	SERIES		2.	PARALLEL		3.	BRIDGE		 P5 P1 P2 P4 P3 + q5 P1 P2 P4 P3

---

* Note that in calculus of probability notation $x\cdot y=P(xy)$ = joint probability of x and $y=P(x)$ $P(y)$ in the event x and y are independent, and $x\mathrm{X}y=P(x+y)=P(x)+P(y)-P(xy)$.

munication channels to a central computer for further processing and assessment. Fig. 6(A) is the block diagram for this simple situation and 6(B) is the applicable redundancy circuit, if R_1 is the probability that radar 1 is operating correctly, R_2 the probability that radar 2 is operating, and C_1 and C_2 are the respective probabilities that the communication channels do not fail. It should be noted that, in this case, the computer will not be provided with correct data if, for example, radar 1 fails and, simultaneously, communications channel 2 fails, even though radar 2 and communications channel 1 are operating correctly.

To increase the reliability of the radar communications system, suppose a "translator" unit is inserted which is designed to process the delayed video output of radar 1 so that it can be multiplexed upon communications channel 2, and similarly process the output of radar 2 for multiplexing upon communications channel 1. Fig. 7(A) is the block diagram for the system including the translator and (B) is the resulting redundancy circuit, where T is the probability that the translator will not fail. If the translator fails to operate, the situation reverts to the previous case.

To illustrate the manner in which numerical computations can be made, assume the following values for element reliabilities of the radar-communications system of Figs. 6 and 7:

$R_1,\ R_2=0.8$
$C_1,\ C_2=0.9$
$T=0.8$

and let H_a be the system reliability without the bridging translator network as in Fig. 6 and H_b, the system reliability with translator included; see Fig. 7. Thus

$$\begin{aligned}H_a&=R_1C_1\mathrm{X}R_2C_2=R_1C_1+R_2C_2-R_1R_2C_1C_2\\&=(0.8)(0.9)+(0.8)(0.9)-\\&\qquad(0.8)(0.9)(0.8)(0.9)=0.922\end{aligned}$$

Note that for the values chosen, each individual radar-communications system has a reliability of 0.72. By using the two radars in parallel, the system reliability has increased to 0.922.

Adding the translator unit yields

$$\begin{aligned}H_b&=T(R_1\mathrm{X}R_2)(C_1\mathrm{X}C_2)+\bar{T}(R_1C_1\mathrm{X}R_2C_2)\\&=T(1-\bar{R}_1\bar{R}_2)(1-\bar{C}_1\bar{C}_2)+\bar{T}H_a\end{aligned}$$

where

$$\begin{aligned}&\bar{T}=1-T,\ \bar{R}_1=1-R_1,\ \text{etc.}\\H_b&=(0.8)[1-(0.2)(0.2)][1-(0.1)(0.1)]+\\&\qquad(0.2)(0.922)\\&=(0.8)(0.96)(0.99)+0.1844=0.945\end{aligned}$$

In this example, the use of the translator increased system reliability from 0.922 to 0.945, even though the translator's reliability was assumed to be only 0.8. Note also that the over-all system reliability is higher than the reliability of any of the individual components. This is not, in general, always true. If the element reliabilities are low, the system reliability may be lower than that of the individual components.

Algebra and Calculus of Redundancies

A form of Boolean algebra can be used, if properly interpreted, to simplify the analysis of redundancy networks. All variables in this algebra are real, posi-

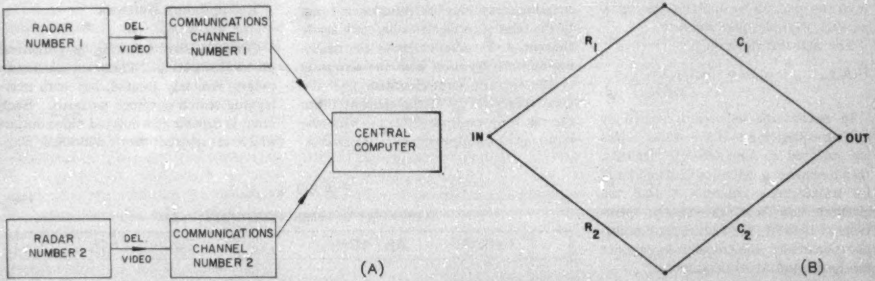

Fig. 6. A—Block diagram of two remote radars feeding data to a central computer. B—Redundancy network for radar-communications system

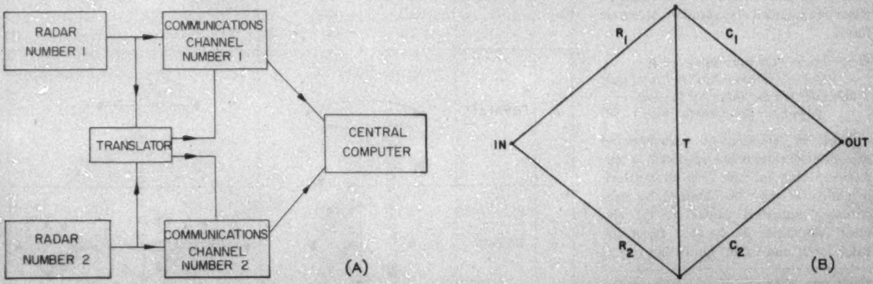

Fig. 7. A—Block diagram of remote radars with translator for cross connections. B—Redundancy network for cross-connected radar-communications system

TABLE II

BASIC OPERATIONS OF REDUNDANCY ALGEBRA

	OPERATOR	SYMBOL	OPERATION	READ AS	ORDINARY ALGEBRAIC EQUIVALENT
1	"OR"	$\oplus$	$A \oplus B$	EITHER A OR B	A+B − 2 AB
2	"AND"	•	A • B	BOTH A AND B	AB
3	"AND/OR"	X	A X B	EITHER A OR B OR BOTH	A+B − AB
4	INVERSION	BAR OVER VARIABLE	$\bar{A}$	"NOT" A	1−A

tive numbers existing in the region between zero and one inclusive, i.e., $0 \leqq A \leqq 1$. There are four basic operators: "or", "and", "and/or", and "inversion." A summary of the basic operations is given in Table II.

The symbol zero signifies absolute certainty of failure and the symbol one means absolute certainty of survival or nonfailure. The inverse of one is zero and the inverse of zero is one. Zero and one combine with redundancy variables in the following manner:

$$
\begin{aligned}
&A \cdot 0 = 0\\
&A\text{X}0 = A\\
&A \cdot 1 = A\\
&A\text{X}1 = 1
\end{aligned}
\qquad (10)
$$

The set of equations 10 are consistent with both the rules of operation given in Table II and the physical interpretation of the operations. Thus, the first equation in 10 states that the survival probability of a system consisting of an element with finite reliability in series with an element that is sure to fail is zero. Similar interpretations may be given for the other equations in the set.

The operations of division and subtraction have no significance in redundancy algebra. It is only after transformation to ordinary algebra by the rules of Table II that these additional operations become meaningful.

The rules for the operation of a variable with itself or its inverse is given in the following set of equations.

$$
\begin{aligned}
&A \oplus A = 0\\
&A \oplus \bar{A} = 1\\
&A \cdot A = A\\
&A \cdot \bar{A} = 0\\
&A\text{X}A = A\\
&A\text{X}\bar{A} = 1
\end{aligned}
\qquad (11)
$$

The proof of the dot and cross self-operations can be obtained from the following reasoning: $A \cdot A$ is the joint probability of A and A, which is the probability of A times the conditional probability of A given A, which is one. Now if $A \cdot A = A$, then $A\text{X}A = A + A - A \cdot A = A$. Similarly, $A \cdot \bar{A} = 0$, since it is impossible for the same element to survive and fail simultaneously just as it is impossible for a flipped coin to show both "heads" and "tails" at the same time. Hence, $A\text{X}\bar{A} = A + \bar{A} - A \cdot \bar{A} = 1$.

By means of these axioms and rules of algebraic manipulation the following identities may be established:

$$
\begin{aligned}
&A \cdot B \cdot C = B \cdot (A \cdot C) = C \cdot (A \cdot B)\\
&\qquad = A \cdot (B \cdot C) = (A \cdot B) \cdot C\\
&A\text{X}B\text{X}C = B\text{X}(A\text{X}C) = C\text{X}(A\text{X}B)\\
&\qquad = A\text{X}(B\text{X}C) = (A\text{X}B)\text{X}C\\
&A \cdot (B\text{X}C) = (A \cdot B)\text{X}(A \cdot C)\\
&A\text{X}(B \cdot C) = (A\text{X}B) \cdot (A\text{X}C)\\
&A\text{X}B + \bar{A} \cdot \bar{B} = 1\\
&(A \cdot B)\text{X}C - A \cdot (B\text{X}C) = \bar{A}C\\
&(A \cdot B)\text{X}A = A\\
&(A \cdot B)\text{X}\bar{A} = AB + \bar{A} = \bar{A}\text{X}B\\
&(A\text{X}B) \cdot (C\text{X}D) = AC\text{X}AD\text{X}BC\text{X}BD\\
&(A \cdot B)\text{X}(C \cdot D)\\
&\qquad = (A\text{X}C)(A\text{X}D)(B\text{X}C)(B\text{X}D)\\
&\overline{A \cdot B} = \bar{A}\text{X}\bar{B}\\
&\overline{A\text{X}B} = \bar{A} \cdot \bar{B}
\end{aligned}
$$

Other identities can be established; however, the foregoing sample demonstrates the type of equivalencies that can be obtained. The identities here are identities in the sense that numerical values can be substituted for the symbols only after the redundancy function has been transformed into ordinary algebraic form. For the redundancy diagram to be usable, it is necessary that every element in the original redundancy diagram be assigned a different symbol even if two or more elements have the same numerical value. Thus, if there are two elements in parallel, both having the same survival probabilities of 0.5, the correct redundancy function is $A\text{X}B$ not $A\text{X}A$. However, once a redundancy circuit, based upon a physically real situation, is established, it is possible to find equivalent networks. As an example of an original network see Fig. 8. An equivalent diagram is shown in Fig. 9. The equivalence is the result of the third identity in the preceding list of identities.

In Table III are listed five pairs of equivalent circuits whose equivalence can be demonstrated by writing the corresponding network functions between terminals of interest for both networks and showing that equivalent expressions can be obtained. To illustrate the method, consider the equivalent pair in item 3, Table III. For the original network

$$
\begin{aligned}
&H_{13} = AC\\
&H_{23} = AB\\
&H_{31} = BC
\end{aligned}
\qquad (12)
$$

For the equivalent network

$$
\begin{aligned}
&H_{13} = (AC)\text{X}(AB) \cdot (BC) = (AC)\text{X}(ABC)\\
&\qquad = (AC) + (ABC) - (ABC) = (AC)\\
&H_{23} = (AB)\text{X}(BC) \cdot (AC) = (AB)\text{X}(ABC)\\
&\qquad = (AB) + (ABC) - (ABC) = (AB)\\
&H_{31} = (BC)\text{X}(AC) \cdot (AB) = (BC)\text{X}(ABC)\\
&\qquad = (BC + (ABC) - (ABC) = (BC)
\end{aligned}
\qquad (13)
$$

Comparing equations 13 with equations 12 establishes the equivalence.

The other pairs may be similarly shown to be equivalent. The pair in item 4, Table III is merely that of item 3 with two additional elements added, one ele-

ment between terminals 1 and 2 and the other between terminals 2 and 3.

Conclusions

It has been shown that if certain simplifying assumptions are made, it is possible to analyze problems reducible to probabilistic networks. The major simplification used was to assume that the elements of the network have independent statistical characteristics, i.e., the probability of failure or survival of one element of a network would not depend upon failure or survival of any other. This assumption is not fundamental. In principle, it is possible by means of more complicated network analysis, to derive network functions in which the assumption of independent failures is not made. The attempt of this study, however, was to give an approach to the solution of redundancy network problems. It has been shown that problems which are reducible to series-parallel and bridge-type networks can be solved in a simple systematic manner.

Appendix. The Factoring Theorem

Given an n element redundancy network connected in any manner whatsoever, having element reliabilities $p_1, p_2, \ldots p_n$, and network function with respect to any two given terminals, $H(p_1,p_2,\ldots p_n)$,

$$H(p_1,p_2,\ldots p_n) = p_k[H(p_1,p_2,\ldots p_n)]_{p_k=1} + \bar{p}_k[H(p_1,p_2,\ldots p_n)]_{p_k=0} \quad (14)$$

where p_k is the reliability of the kth element.

Proof: If $H(p_1,p_2,\ldots p_n)$ is a function representing a real network, then it can be expressed in canonical form. When written in canonical form, note that every term must contain either p_k or $\bar{p}_k$ but not both. Let H_a be the sum of those terms in the canonical equation which contain only p_k, and H_b the sum of those terms which contain only $\bar{p}_k$. Since H_a contains only terms with p_k, p_k may be factored out, giving

$$H_a = p_k H_s \quad (15)$$

Similarly,

$$H_b = \bar{p}_k H_0 \quad (16)$$

But

$$H(p_1,p_2,\ldots p_n) = H_a + H_b = p_k H_s + \bar{p}_k H_0 \quad (17)$$

Now, neither H_s nor H_0 contain either p_k or $\bar{p}_k$; therefore, setting $p_k=1$ for both sides of equation 17 yields

$$[H(p_1,p_2,\ldots p_n)]_{p_k=1} = H_s \quad (18)$$

since for $p_k=1$, $\bar{p}_k=0$.

Similarly, setting $p_k=0$, for which $\bar{p}_k=1$, yields

$$[H(p_1,p_2,\ldots p_n)]_{p_k=0} = H_0 \quad (19)$$

Combining equations 18 and 19 with 17 gives

$$H(p_1,p_2,\ldots p_n) = p_k[H(p_1,p_2,\ldots p_n)]_{p_k=1} + \bar{p}_k[H(p_1,p_2,\ldots p_n)]_{p_k=0} \quad (20)$$

which proves the theorem.

OPERATIONS RESEARCH can be of value to the communication engineer by enabling him to set up valid criteria by which to judge the relative advantages of communication systems in specified applications. While in many cases insufficient data are available for an exact analysis or optimization, this approach is superior to the classical method of choosing arbitrary evaluation parameters which may be meaningless in the proposed application. On the other hand care must be taken in the interpretation of the results of an operations research procedure. In the classical approach the system is designed to meet some given specifications and is not optimum in any particular sense. In an operations research approach criteria of performance and effort, plus constraints, are chosen, and the system is optimized with respect to these quantities. However, because of necessary simplifications in both the criteria and the constraints the results are only pseudo optimum with respect to the desired applications. In effect, the ambiguities involved in choosing the specifications of a classical approach may have been exchanged for the ambiguities involved in choosing the criteria and the constraints in an operations research approach. Nevertheless, an operations research approach is desirable because it helps prevent unintentional ambiguities from entering the problem by directly focusing attention on the application as well as the system.

Historical Background

Operations research is as old as science and management. Its development as a recognized form of research, however, was in response to the military needs of World War II. In this activity scientists were attached to the staffs of military organizations for the purpose of giving scientific advice on those matters which were not handled by the service technical establishments. The staffs of the military provided the scientist with the operational outlook and data, and the scientists applied the scientific methods of analysis to these data and were thus able to give useful advice. The scientist used as data the material to be found in an operation room, e.g., signals, track charts, combat reports, meteorological information, etc. Experience showed that the analysis of operations in a more scientific manner than is done normally by service specialists or officers was of utmost value. This was especially the case with those aspects of operations into which probability and statistical considerations enter.

One important application of operations research during World War II dealt with the systematic evaluation of enemy countermeasures.[1] Without this objective evaluation the tendency was to credit the enemy with an effective countermeasure before it was actually developed. For example, consider the question of installing early-warning radar on submarines. A radar set which could detect airplanes farther off than lookouts would enable the submarine to dive in time to escape detection. On the other hand, many submarine skippers were convinced that the Japanese planes were equipped with radar receivers and were thus detecting the submarines by means of the radar signals. This view was based on the fact that more Japanese planes came into view when the early-warning radar was on than when it was off.

The radar should "see" more airplanes because its radius of detection is greater. In fact, if the planes are not exploiting the radar signals, the ratio of the numbers of aircraft seen with and without the radar will equal the ratio of the corresponding radii of detection. Since the data confirmed this, early-warning radar was used on U.S. submarines. As a result, in spite of the fact that the first early-warning radar improved the detection range by only 40%, U. S. submarines were caught on the surface in less than 5% of the attacks. The Japanese, on the other hand, did not install radar and U.S. planes enjoyed a 50% chance of surface attack.

Since World War II, operations research has been applied increasingly to the solution of problems of both military and commercial interest such as traffic delays at toll booths,[2] New York's subway fare structure,[3] combat stress in Korea,[4] supermarkets,[5] and the hand setting of type in the printing industry.[6] One example of a commercial application is in the realm of hotel management. At any given time a hotel has a number of guests in residence and a number of advance reservations. How many additional reservations should the booking clerk accept? If he turns away all reservations when the hotel is filled on paper, he will rarely have a filled hotel, for on the average about one out of five reservations never show up. On the other hand, he cannot always accept all reservations, for occasionally he will be called on to house more people than the hotel has room for. He must somehow balance the gain in having a large number of rooms rented against the loss in good will of occasionally failing someone who has been given a reservation. As soon as the hotel manager has decided how much such a failure costs the hotel, the other factors in the analysis involve only straightforward probability analysis. The computation of the mean-stay of a guest and its relation to the check-out rate of guests already present, the curve for hotel reservation cancellations, the dependence of fluctuations on time of week, and so on can be reduced to a fairly simple set of rules for the booking clerk to follow in making his day-by-day decisions.

Principles of System Evaluation

In a fully developed operations research process four fundamental steps or actions are necessary: (1) choice of criterion of performance, (2) choice of measure of effort, (3) more or less explicit setting up of a model, and (4) optimization. Of these four actions the selections of a criterion of performance and a measure of effort are the most important. These are the crucial steps in operations research because the concept of value and the standard by which the relative importance of the results can be judged is involved. In the strictest sense those quantities which suitably measure the performance and effort of a system cannot be precisely defined unless the exact employment of the system and the utility evaluation of the decisions are both known. In most instances, therefore, the high-level problem of over-all optimization is extremely

difficult and suboptimization of the system components is sought instead.

Frequently one of the most important contributions of an operations research approach lies in determining the proper criterion of performance and measure of effort. That the criteria chosen greatly affect the conclusions can be seen by considering the problems the British had in World War II in deciding whether or not to install antiaircraft guns on merchant vessels.[1] The installations of antiaircraft guns on merchant vessels were not only expensive, but in many cases the guns were needed elsewhere. Moreover, the guns were relatively ineffective so far as an aggressive criterion was concerned because, with inexperienced crews, planes were shot down in only 4% of the attacks. This seemed to indicate that the guns should not be installed. However, as further data were taken, it became apparent that the proper criterion was not the number of planes destroyed but rather the protection the gun afforded the ship. Analysis showed that the accuracy of the attacking plane was reduced by the gun fire, so that the chance of the ship being sunk was reduced in half. This greatly favored the installation of the guns and decided the question.

However, the defensive criterion of protecting the ship is not really the criterion used in this low-level problem. If it were, the conclusion would be not to install the guns but to keep the ships in port. Criteria such as this, which must be hedged to present absurd results, should be avoided. Instead the high-level approach should be considered, namely, whether the installation of guns on merchant ships would aid the conduct of the war, and the low-level criteria chosen so as to be consistent with the high-level criteria. A suitable criterion in this case would combine the cost of installations against the increased number of successful trips and the materials lost when ships were sunk. That operation which minimized a total cost such as this would be optimum.

The third and fourth actions in an operational research analysis deal with the procedural steps involved in evaluating given situations once the figures of merit and the measures of effort have been set up. It has been unfortunately true that whereas the choice of criteria and measures of effort are central to the operations research problem, almost all the effort thus far has been devoted to the purely procedural phases involved in actions 3 and 4. An important reason is that technical workers are of the conviction that since philosophizing about criteria involves value judgments, it is not science and, therefore, not quite respectable. As long as value judgments remain not-science, however, operations research cannot be science either.

Application to Communication Systems

In the remainder of this paper an attempt is made to suggest a method of obtaining a criterion for evaluating the performance of communication systems, a criterion whose use, it is hoped, will result in more than suboptimization. Perhaps, by means of this criterion it will be possible to evaluate system performance quantitatively in an economic sense. In evaluating communication systems one must realize that the purpose of a communication link is to transmit correct messages. Unless this restriction is made one has the philosophical problem of handling situations where a wrong message may be better than the right one, and where the worth of a communication changes with hindsight. It should be noted that an operations research approach to the communication problem is based on evaluating the future behavior and worth of a system in terms of present knowledge concerning the proposed applications.

For purposes of analyzing the over-all operational situation it is convenient and conventional to consider the system as two sequential actions: that of transmitting information, and that of acting on the received information. When the behavior of the action link is unknown, the communication link must be characterized by the conditional probabilities relating all the possible perturbations of one symbol into another. Only by including this information can an over-all performance measure be evaluated for particular rather than average messages, as for example, by specifying both the mean and the confidence limits on the expected utility. This is of concern when a particular communication may be of extreme importance and certain message perturbations must be avoided or be under control.

As in many analogous instances, however, one is willing to forego accuracy for simplicity. In this instance, since the short-term employment of the system and the utility evaluations of the resulting actions are usually only vaguely known, foregoing accuracy in the specifications of the communication link may result in only a small change in the over-all accuracy of the performance measure. Hence concern is conventionally limited to average message reliability parameters and average employment characteristics. This approach permits an integrated parameter to be substituted for the many conditional probabilities otherwise involved. Which integrated parameter is actually indicative of the over-all reliability still depends, of course, on the worth of the behavior based on the received signal.

In conformity with this viewpoint two costs may be considered: (1) the mean communication cost or measure of effort associated with the transfer of information, and (2) the mean risk cost associated with the resulting decisions.

Communication cost is determined by the design and operation of the equipment and thus indirectly by the power, bandwidth, and time requirements. It also depends on the expected operational conditions of message density, the method of modulation, and the system of information coding. Risk cost, on the other hand, is a function of the receiver's ability to distinguish signal from noise or the transmitter's intent from the interference. In general, increases in power, bandwidth, and time decrease the risk cost and increase the communication cost.

In the optimization problem the actual communication cost is evaluated by knowing the fixed costs as well as the operational environment in which the system performs. The risk cost is determined from knowledge of the manner in which the messages are perturbed by interference and the cost of resulting wrong decisions. The total cost may then be considered the sum of the communication cost and the risk cost and the best system operation determined by standard minimization procedures. In this manner, minimum costs can be determined for other systems and comparisons made among them. The nature and interrelation of these two costs is now considered.

Communication Cost[7]

In establishing communication cost relationships, one must include initial construction and installation costs, maintenance costs, and operational costs. Initial and maintenance costs are fixed costs and do not vary significantly with the operational situation in which they are used. On the other hand, operational costs, as defined here, are functions of the operational conditions.

A necessary first step in a cost formulation is to make a statement of preferences. In terms of cost this means that relative weightings are assigned to the basic parameters of the communication problem.

Relative weightings enter because, depending on the operational situation, the basic parameters may have different relative importance. In communication systems three parameters are of fundamental importance and may be considered as basic parameters. These are signal power, signal bandwidth, and operational time. Time, as used in this context, has two aspects. One aspect refers to the transmission time of the messages over the channel. This aspect is a function of the information, the information rate, and the coding delay. The other aspect refers to the waiting time and is a function of the percentage of full loading of the facilities and the number of communication channels. This latter aspect is concerned with traffic density and problems of congestion such as arise in telephone operation and in aircraft control at large airports. Transmission of information thus results in an information time delay, while loading results in waiting time delay. The sum of these time delays is called the operational time.

Initial cost is a function of power, because power output determines the size and weight of a transmitter; it is a function of bandwidth, because bandwidth determines the size, character, and number of components; and it is a function of time, because time, when utilized in a trade-off with power and bandwidth, implies the use of coders, decoders, and noise filters. Maintenance cost is a function of all three basic parameters, because they determine equipment complexity. Operational cost, however, is determined by the relative importance of the basic parameters in the operational situation.

As an example consider the problem of supplying a walkie-talkie to a combat patrol. There are initial costs of construction, installation costs of delivery, and maintenance costs. In actual use the equipment has an operational cost due to such factors as its weight and bulk (i.e. a rifle in place of the walkie-talkie might be preferred), the possibility of the signal being detected by enemy forces, and the possibility of its interfering with other communication equipment. These factors are reflected in the signal bandwidth and power. Indeed, to keep these costs low the bandwidth and power output of a walkie-talkie is fairly low although the operational time, i.e. the number of times a message is repeated to assure transmission, may be fairly high.

RISK COST

Risk cost is concerned with the reliability of system operation and also is a function of the basic communication parameters of power, bandwidth, and time. Risk cost enters because in the reception of information over a noisy communication channel, decisions must be made according to some criterion. These decisions can be made according to any one of several criteria, but it can be shown[8] that there is a best decision rule, in the sense of minimizing the average risk, once the statistics of the noise and signal are known. Errors will be made, however, even under the best decision rule.

It is these errors in decision which produce the risk cost, since they can have bad consequences in the operational sense. For example, errors due to noise in a control link of an antiaircraft system might cause the incorrect aiming of a gun which is attempting to hit a bomber. The reward for obtaining correct control information is the destruction of the bomber, while the penalty for incorrect control information is serious damage to ground installations. Since the reward for a correct decision is, in general, in different units than that of the penalty for an incorrect decision, some universal performance measure is desired. Such a measure may be obtained by assigning a cost or utility value to each decision, i.e. to every combination of system input and system output. As mentioned previously, such assignment of cost to each decision is usually not practical. Hence it is desired to determine the cost of average performance. This may be done by substituting an integrated reliability parameter for the complex of associated conditional probabilities. Several possible reliability parameters which may be used are: rate, per-unit equivocation, accuracy, error probability, average error per bit of information, and generalized error probability. In some instances, of course, none of these parameters may describe the situation. As an extreme case, for example, the entire asset of a walkie-talkie may be in the increased morale of the patrol and errors in transmission may have, within large limits, negligible effect.

One convenient bound on the performance of communication systems is that presented by Shannon.[9] The significance of this result is that if infinite coding delays are permissible, and equipment complexity is of no consideration, error-free messages may be sent even through a noisy communication link. The only effect of the noise is to limit the maximum information rate which can be handled by the channel. Since in general the coding delay and equipment complexities are important, actual transmissions cannot in general be error-free. One interesting exception to this rule is an information feedback system where there is a noise-free feedback path of at least the same capacity as the noisy direct channel.[10]

In the general information feedback system the receiver suitably confirms the received information and the transmitter decides whether or not the receiver has properly interpreted the message. From the viewpoint of reliability, information feedback can therefore accomplish a great deal, particularly if the feedback channel is error-free. The term "information feedback" is used to distinguish this form of feedback from decision feedback[11] where the receiver decides whether or not the received message can be properly interpreted and then reports its decision to the sender.

A simple information feedback system is an iterative discarding system in which the feedback process is used to improve the confirmation denial information as well as the main message. For example, the system can operate as follows. If the feedback message indicates that an incorrect direct channel message was received, the sender transmits an erasure signal followed by the correct message. If it is indicated that an erasure was incorrectly received as a message, the sender transmits two erasures to erase both this incorrect message and the preceding incorrect message. When a message is received as an erasure, the sender merely transmits the preceding message and the intended message. If the feedback is error-free and totally distinctive, all errors will eventually be corrected and the final message will be error-free. The unique feature of this system is that error-free transmission can be obtained without infinite delay, whereas this result may never occur in unidirectional systems. The main penalty for this error-free transmission lies in the fact that the discarding process discards large amounts of information at low signal-to-noise ratios. Thus there exists a threshold signal-to-noise ratio below which the information rate becomes zero.

In this nontruncated feedback system the final message is error-free, but there exists the possibility of large storage delays before a message is finally accepted, and such delays may exceed the memory capacity of the equipment. Hence in a practical communication channel, there will be some maximum number of repeats which cannot be exceeded, so that the deterioration in system performance due to truncation of the feedback process is of interest.[12] As expected, the primary effect of truncation is, of course, to prevent error-free transmission.

Except for special situations, which do not occur in practice, a message will not be error-free, and thus some risk parameter must be chosen to describe the worth of the system to the receiver. Several such parameters are described in the following.

(*a*). *Rate, Per-Unit Equivocation, and Accuracy*

For example, consider a communication channel which is being used to transmit the results of a chance situation to a gambler before these results become common knowledge, so that the gambler may place bets at the original fair odds.[13] By placing suitable bets the gambler may, with probability one, insure that his capital will increase at an exponential rate, the exponent being exactly the Shannon information rate. Since the information rate is given by

$$R=H(x)-H_y(x)$$

where $H(x)$ is the information of the informer and $H_y(x)$ the information destroyed by the noise in the channel, a suitable measure of the usefulness of the channel to the receiver is the information rate or the ratio of $H_y(x)$ to $H(x)$, i.e. the per-unit equivocation. In fact, any communication system which utilizes all a posteriori probabilities, and whose purpose is to increase the chance of winning in a situation where the loss, if incorrect, and the gain, if correct, is proportional to the amount invested, can be characterized by per-unit equivocation as a reliability parameter.

Another form of a risk measure based on rate is accuracy. Accuracy was originally introduced by Laemmel[14] and is defined as the information rate divided by the error entropy in bits per symbol, i.e.,

$$A=\frac{R}{H_z(y)}=\frac{H(y)-H_z(y)}{H_z(y)}$$

This ratio can be shown to behave similar to signal-to-noise ratio for certain systems, varying between 0 and ∞ as reliability increases.

(*b*). *Probability of Error*

Another reliability parameter which is widely used is probability of error. The general class of situations for which probability of error is applicable is that for which the mathematical model can be simplified to the extent that only one conditional probability is necessary to specify the system. That is, all kinds of errors are considered equally bad, or a uniform risk cost is associated with all wrong decisions. Then, while the worth of the system may be a complicated function of the error probability, it is nevertheless true that specifying one specifies the other. This concept may be illustrated by an antiaircraft gun example. If a significant hit probability exists only when the gun receives correct control or direction information, then all control errors will result in missing the bomber, thus incurring equal risk costs.

For an unidirectional system the average error probability may be obtained by averaging over the error probabilities associated with each possible input signal, For a bidirectional or feedback system the concept of a generalized error probability, discussed in section *d*, may be necessary.

(*c*). *Average Error Per Bit of Information Transferred*

The average error per bit of information is a risk parameter that attempts to combine both rate and error probability concepts. By definition

$$\xi=\frac{P_e}{R}=\frac{P_e}{H(x)(1-E)}$$

where E is the per-unit equivocation, $H_y(x)/H(x)$, and P_e is the probability of error. This risk measure also shows the desired behavior with reliability, i.e., for reliable systems P_e becomes small, and ξ approaches zero. Conversely, ξ becomes large for a poor system. The measure is easy to calculate provided R is given. However, since R is a nonlinear function of P_e, the knowledge of P_e, except in certain isolated cases, permits the rate of information to be only approximated. Also, if R and ξ are given, it is not possible to state the exact amount of information lost, but bounds on lost information for specific systems can be obtained. For example, bounds on equivocation and error entropy can be determined for b-level pulse-amplitude-modulated systems having fixed P_e.[11]

(*d*). *Generalized Error Probability*

The direct extension of the error probability concept to communication feedback systems,[15] whether they be information, decision, or compound feedback systems, cannot be made because, in general, there is a nonconservation of message length and thus no one-to-one correspondence exists between the input and output symbols comprising the message. As an example, consider the information feedback system previously described where 0 and 1 are the input message symbols and φ the erasure symbol. To send a simple message, such as (0 1 0), the actual transmission, in the case of noisy feedback, could be

Direct channel message transmitted........................0 φ 0 1 0

Direct channel message received and repeated in the feedback channel........................0 0 0 1 0

Feedback message received......1 φ 0 1 0

In this case, corresponding to the transmission of a 3-digit message, not only are five digits received and accepted, but one error in transmission has occurred in the direct channel and two errors in the feedback channel. On the other hand, if the actual transmission is

Direct channel message transmitted. .0 1 0

Direct channel message received and repeated in the feedback channel.....0 φ 0

Feedback message received.........0 1 0

the received message contains only one unerased digit. To complicate matters further the actual transmission could be such that errors in transmission are made, but the received message is correct after the erasure process has been applied.

In order to account for these possibilities the error probability concept must be generalized. One such generalization is based on considering the entire message as being right or wrong. Consider, for example, an unidirectional system where there is no intersymbol constraints and a one-to-one correspondence between the input and output symbols. Then the probability of a message of M symbols being correct is

$$Q_{\text{message}}=(1-P_{\text{symbol}})^M$$

where P_{symbol} is the error probability per symbol. This indicates an exponential rate of decrease, with increasing message length, in the probability of a message being correct. It suggests that for long messages P_{symbol}, defined as

$$P_{\text{symbol}}=\lim_{M\to\infty}\{1-(Q_{\text{message}})^{1/M}\}$$

be considered as a generalized error probability per symbol. In comparing systems, whether they are unidirectional or bidirectional, the system having the smallest generalized error probability per symbol will, for long messages, have the greatest probability of correct transmission.

This presumes, of course, that the probability of a message of M symbols being correct, for the systems under consideration, decreases exponentially with increasing message length. In this event Q_{message} has the form

$$Q_{\text{message}}=f(M)e^{-\alpha M}$$

where the error exponent α is not zero and $f(M)$ is always less than M^n for some finite n. The evaluation of P_{symbol} then constitutes the evaluation of α, larger values of P_{symbol} corresponding to smaller values of α. Specifically

$$-\alpha = \lim_{M\to\infty}\left\{\frac{1}{M}\ln Q_{\text{message}}\right\}$$

or

$$-\alpha = \ln(1-P_{\text{symbol}})$$

The actual evaluation of the generalized error probability can be done by considering an input message of length M. The probability of such a message being received correctly is then determined, and the corresponding average probability of receiving messages of length M correctly is found by averaging over all messages of such length. The process is then repeated for longer messages and the asymptotic value of $1-(Q_{\text{message}})^{1/M}$ determined. This then corresponds to the generalized error probability per symbol.

It should be noted that the choice of a risk measure in some instances may not be obvious, and any one of several might give significant comparative results in system evaluation. The foregoing remarks are presented to point out some of the various measures that do exist, and for which in some operational environments one form might be clearly more applicable than another. The advantages or disadvantages of using one risk measure rather than another lies solely in its suitability to describe a situation more accurately.

COMBINED COMMUNICATION AND RISK COST

In obtaining a complete evaluation of a system, both communication and risk costs play a part. The total cost for the system is the sum of the two costs, accounting for the salient factors in a communication situation. Thus, for a particular system, the average total cost is

$$C=\int_L\int_N P(N;L)[C_r(N;L)+C_c(N;L)]\,dN\,dL$$

where $P(N;L)$ is the probability of the noise or interference being N when the operational situation, such as the message density, is L, C_r is the corresponding risk cost, and C_c the communication cost. In general the evaluation of the risk cost is itself an averaging process over all possible message alterations that can occur in transmission. Thus, for example, when a discrete set of messages is employed, and the error probability is a significant risk measure,

$$\begin{aligned}C_r(N;L)&=C_r(P_e;L)\\&=C_r\Big(\sum_m P(m)P_e(m,N);L\Big)\end{aligned}$$

where the error probability P_e must be evaluated by averaging the probability of a particular message m being transmitted, $P(m)$, against the probability of that message being received in error, $P_e(m,N)$, when the interference is N. Since in general the risk cost is reduced if the error probability is reduced, a method which so reduces the error probability at a "small" increase in communication cost is considered valuable as a suboptimization. Actual optimization must, of course, evaluate the performance in terms of the total cost. This requires that the total cost be written in terms of perhaps power, bandwidth, and time as basic parameters. By setting

$$\frac{\partial C}{\partial P}=0,\qquad \frac{\partial C}{\partial W}=0,\qquad \frac{\partial C}{\partial T}=0,$$

the actual power, bandwidth, and time at which optimum performance results can be obtained. The system specifies the error probability P_e, but the cost relationships must be determined by collection of sufficient pertinent data. This process is thus one which rightly falls into the realm of operations research, where the necessary weighting of the merit parameters must be obtained from a study of past and current operations and introduced into the theoretical model of the situation. Once the model has been found to be a valid representation, the values of the parameters may be altered in order to predict the effects of new courses of action.

◆

Discussion

R. Krzyczkowski (Westinghouse Electric Corporation, Baltimore, Md.): The authors deserve to be congratulated for their skillful introduction to operations research. However, I do not think that they have done justice to the subject for it is simply impossible in the context of one brief paper. The art of operations research (or is it science?) is very wide and grows with increasing acceleration. Thus, all references quoted in the paper date between 1954 and 1956. Recently, I completed a 2-week operations research course at the Johns Hopkins University; they considered their own texts, issued in 1956, as obsolete and gave us a new book just published.

Operations research has very many applications in communications not solely of economic evaluation nature. In our organization, teams engaged in over-all military systems design comprise not only engineers, mathematicians, and economists, but also military experts and human engineers, and we think that a lawyer and a sociologist could be usefully and fully occupied. Authors seem to be under the influence of the somewhat dessicated mathematical Massachusetts Institute of Technology school of operations research. We, probably under the influence of Johns Hopkins, tend to think that the wide, Case School approach may be more appropriate for telecommunication systems, that is, for man-machine systems.

However, to confine myself to the paper under discussion, the authors' choice of basic parameters of power, bandwidth, and time as main factors in the cost function is very interesting and theoretically gives opportunity for very elegant mathematical treatment. Certainly it establishes judgment criteria. Unless authors can unveil

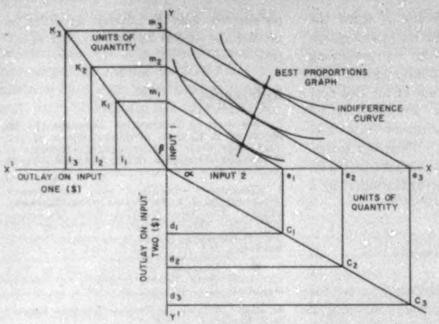

Fig. 1. Construction for finding the least outlay combination

practical results obtained, though, I am somewhat sceptical as to the usefulness of this tool for actual designs of systems or equipment.

First, if parameters are restricted to three (power, bandwidth, time) or even four (adding reliability), equipments cost compared must be of the same class. They must be all radio, for instance, and not cable versus radio as parameters immediately lose their significance. Moreover, if we consider radio, say, equipment should be of the same type, e.g. troposcopic scatter, work in the same frequency band, and in general be quite similar.

Similar work is no doubt carried out in several organizations. At Westinghouse, I made a comparison of competing scatter systems using the same principle. However, my parameters were less "theoretical." I used power transmitted, amount of diversification, diameter of antenna, and receivers' noise figure. These four were most significant from cost point of view.

In a recent paper[1] I used the same method and actually gave dollar cost figures for 18 different cable systems. Four parameters are involved: size of cables; number of cables; facilities offered; and transmission techniques used. I chose these after a long struggle with ideas like dollars per decibel or dollars per kc. In my experience they were just not helpful as soon as different systems had to be compared.

The cost equation is not the only approach to function minimization. Some 3 years ago I applied the indifference curve/price line diagram technique, as evolved by professional economists such as Stigler, Samulson, and Boulding here, or Hicks in England, to communication systems design purposes.[2] The principle of such a construction is shown in Fig. 1. Input *1* is, say, power; input *2*, bandwidth. Each indifference curve represents a series of systems which are equally good, or bad, systems where trading of some power results in gain in bandwidth. The higher the curve, the better the system. Straight lines are price lines; they show how much you can afford to spend on the system. Obviously you tend to choose the highest curve, and the tangency point gives you the best combination of the two inputs. The diagram is 2-dimensional but algebraically one can treat any number of parameters; Lagrange multipliers are most useful in this calculation. In my experience, this method is very useful, especially for problems concerning growing systems.

On Coding for the Binary Symmetric Channel

A. B. FONTAINE
ASSOCIATE MEMBER AIEE

W. W. PETERSON
ASSOCIATE MEMBER AIEE

QUESTIONS concerning coding for the binary symmetric channel might be divided into three categories:

1. For a specified error probability and with no restriction on the length of a code, what is the maximum rate at which information can be transmitted, i.e., what is the channel capacity?

2. For a specified code word length n and a specified rate less than the channel capacity, what is the error probability for the optimum code?

3. How can optimum codes, or at least good codes with a given rate and word length be constructed?

The first question was answered by Shannon.[1] The second question has been answered to a large extent by Slepian[2] and Elias[3–5] and in an unpublished paper by Elias. Slepian has compiled a table of optimum group alphabets for codes of small n. Elias has given upper and lower bounds on the probability of error for optimum alphabets for the binary symmetric channel. These upper and lower bounds are very close over a wide range of rates for large n, but for values of n in the order of the upper limit in Slepian's table, the upper and lower bounds may differ by several orders of magnitude. Codes in this range are now being considered for use in practical systems.

The third question, that of finding optimum codes, or at least good codes, is the most difficult. Slepian's table of optimum group alphabets is a good start. To it can be added Golay's "lossless code"[6] with 23 bits of which 12 are information bits. The Hamming codes[7] are optimum and codes described by Reed[8] and MacDonald[9] are at least good codes; and among all three types are arbitrarily long codes. Hamming's codes are high-rate codes—as n approaches infinity, the ratio of the number of check bits to the number of information bits approaches zero. Reed's and MacDonald's codes are both low-rate coding systems—as n approaches infinity, the ratio of the number of information bits to the number of check bits approaches zero. There are, however, virtually no results for the middle range of rate except for small values of n.

The principal results in this paper deal with medium length codes in this middle range of rate. Elias' bounds on error probability involve some approximations which are made for the sole purpose of obtaining an end formula from which cal-

culations can be made readily. Calculations in which some of these approximations were not used were made on the IBM (International Business Machines Corporation) *704* for the middle range of n, and hence resulted in tighter bounds than those given by Elias' end formulas. These numerical results are presented in the section on "Bounds on the Probability of Error" and, for specific cases, are useful principally as guides in interpreting Elias' bounds.

The most interesting results are presented in the Section on the "Evaluation of Actual Codes on the 704." The IBM *704* computer was programmed to evaluate probability of error for binary group alphabets with n as large as 72 (and with no more than 20 parity check bits). The *704* was used for two general purposes: first, to aid in proving more codes to be optimum, thus extending Slepian's table; and secondly, to aid in studying random codes.

The possibility of using random codes has often been mentioned. Most randon codes are good since the average error probability for random codes is in general near optimum. The real difficulty lies not in generating a random code, but rather in determining just how good a specific random code is. Now, using the *704*, it is possible to generate fairly long random codes, evaluate them, and select codes which are good.

Review of Binary Coding Theory

The pertinent aspects of the theory of binary codes are reviewed briefly here. The codes with which this paper is concerned are block codes for the binary symmetric channel. The binary symmetric channel is a communication channel which transmits two symbols, represented by the binary digits *0* and *1*, with equal probability q that the received symbol will be the same as the transmitted symbol, and probability p that the received symbol will be the opposite of what was transmitted, i.e., that an error will occur. The errors are assumed to be independent.

A block code is a code using sequences of binary digits, *1*'s and *0*'s, of a fixed length n. Only certain selected sequences, called code points, are transmitted. During transmission certain of these binary digits may change, i.e., errors may occur. If a given code word is transmitted, the probability that it will be received with no error is q^n. The probability that there will be one error in a specified position is pq^{n-1}. The probability of i errors in i specified positions is p^iq^{n-i}. If $q>p$, the received block with no errors is more likely than any specified sequence with one error. Any received sequence with one error is more likely than any specified received sequence with two errors, etc.

At the receiver a decision must be made as to which code point was transmitted, i.e., the received sequence must be decoded. This might be done according to the system illustrated in Fig. 1. The code points are listed in a row across the top of the table, and under each code point are listed all other sequences of n binary digits which will be "decoded" into the given code point.

The probability of error for a code can be calculated from a table such as that shown in Fig. 1. The probability of correct decoding if a given code point is transmitted equals the probability that the received sequence is one listed under the transmitted code word. For example, consider column two in Fig. 1. The code point itself involves no errors, and hence has probability q^n. The next five sequences down the list result from single errors and hence have probability pq^{n-1}. The last two are double errors and hence have probability p^2q^{n-2}. Thus the total probability of correct decoding if this code point is transmitted is

$$Q=q^n+5pq^{n-1}+2p^2q^{n-2}$$

For the code as a whole the probability of error is the average probability of error for all the code points. If the code points are used with equal frequency, this is the sum of the error probabilities for the individual code points, divided by the number of code points.

Block codes can be subdivided into parity check and nonparity check codes. For the most part this paper deals with parity check codes. In such a code k positions are used as information positions and in them all combinations of ones and zeros are permitted. The symbols in the remaining $n-k$ positions are determined from the information bits by "parity checks." The code shown in Fig. 1 is a parity check code. The first two places are information bits. The fourth bit is a parity check on both information places—it is one if there are an odd number of ones in information places, zero if there are an even number of ones in information places. The third bit is a parity check on the first bit only, the fifth bit a parity check on the second bit only.

For a parity check code the optimum decoding scheme is as follows: The decoding table (for example, Fig. 1) when completed will list each sequence once and only once. The code points are listed in the first row with the word consisting of all zeros first. Then of all the remaining sequences the one with the fewest ones in it (or any one of these if there are several) is placed under the code point consisting of all zeros. This sequence represents an error pattern, since each *1* in the sequence represents an error in that digit. Next under each of the other code points is listed the sequence which would result if the same error pattern should occur with the code point in question. The row of sequences formed in this manner is called a "coset," and the sequence under the first code point (00000) is the "coset leader."

A third row is formed using as its coset leader an unused sequence with the fewest ones, and similarly a fourth row, fifth row, and so on until all sequences of n binary digits are used. The complete table is called a "standard array." In the basic theory of "group alphabets" described by Slepian, it is proved that such a scheme is without duplications and represents optimum decoding.

Since the sets of error patterns which are corrected are the same for all code points in a parity check alphabet, the probability of correct decoding is the same for all code points. In fact, this probability can be calculated if only the sequences in the first column, i.e., the coset leaders, are known. For example, in the code shown in Fig. 1, the first sequence in column one has weight zero, i.e., it has no 1's. The next five sequences have weight one, and the last two have weight two. The probability of correct decoding for the code point of all zeros, and therefore for every code point, is

$$Q = q^5 + 5pq^4 + 2p^2q^3$$

Since a parity check code has k information places each of which may be zero or one, there must be 2^k code points. There are 2^n different sequences of n binary digits. Hence there must be 2^{n-k} cosets.

Bounds on the Probability of Error

The probability of error P_{opt} for an optimum parity check code for the binary symmetric channel, given the probability of error for the channel, the length of the transmitted sequences, and the number of information digits in a transmitted sequence can be bounded by $P_t \leq P_{opt} \leq P_{av}$. Recent papers of Elias[3-6] give expressions for P_t and P_{av}. To simplify these expressions, Elias obtains upper and lower bounds and asymptotic expressions for P_t and P_{av}. From the bounds for P_t and for P_{av}, he draws some very interesting and important conclusions regarding the exponential behavior of P_{opt} for large n. The meaning of the bounds P_t and P_{av} will be reviewed in this section. In addition, values calculated from a lower bound for P_t will be compared with those calculated from the exact expression for P_t; and values computed from the upper bound for P_{av} will be compared with those computed from a lower upper bound for P_{av} to give a clearer idea of the range of usefulness of these expressions. There is also an upper bound for P_{opt} which is due to Gilbert.[10] This also will be discussed and evaluated for several values of n, k, and p.

THE LOWER BOUND P_t

Suppose that for a given code and decoding scheme the list of sequences which decode into each code word includes all error patterns with fewer than j errors, some error patterns with j errors, but none with more than j errors. Then moving one sequence from the column under one code word to the column under another decreases the probability of correct decoding by p^jq^{n-j} for the first word, and increases the probability of correct decoding by no more than this amount for the second code word. This procedure cannot possibly increase the average probability of error (if the code words are used with equal frequency). Thus such a code is clearly as good a code as can be found with the same number of code words and block length. The code described in Fig. 1 is such a code.

Such codes do not exist for most values of block length and number of code points. Whether they do or not, clearly no code could have a greater probability of correct decoding than would be calculated, assuming such a code were possible. This fact provides the lower bound on the probability of error found by Elias:

$$P_t = 1 - \sum_{j=0}^{k_1-1} \binom{n}{j} p^j q^{n-j} + \left[2^{n-k} - \sum_{j=0}^{k_1-1} \binom{n}{j}\right] p^{k_1} q^{n-k_1} \tag{1}$$

where k_1 is the integer defined by

$$\sum_{j=0}^{k_1} \binom{n}{j} \geq 2^{n-k} > \sum_{j=0}^{k_1-1} \binom{n}{j} \tag{2}$$

Elias' bounds for P_t are

$$P_t \geq \frac{q_1 p}{\left(p_1 + \frac{1}{n}\right) 2q\sqrt{2np_1q_1}} \times 2^{-n[H(p^1) - H(p) + (p_1 - p) \log q/p]} \tag{3}$$

$$P_t \geq \frac{p_1 q}{(p_1 - p)\sqrt{2\pi n p_1 q_1}} \times 2^{-n[H(p_1) - H(p_1) + (p_1 - p) \log q/p]} \tag{4}$$

where $p_1 = k_1/n$ and $p_1 + q_1 = 1$ and $H(p) = -p \log p - q \log q$

THE UPPER BOUND P_{av}

A random code is formed by selecting the code points at random from the possible 2^n sequences. The code points are selected independently with all of the 2^n sequences equally probable. Received sequences are decoded into a code point which differs in the fewest positions from the received sequence. The average probability of error for random codes is defined as P_{av}. It is found by averaging the probability of error for the decoded word over all code points in any particular code and over all possible codes, with equal weights given to each code point and to each code. P_{av} provides an upper bound for P_{opt} since at least one of the random codes must be as good as the average. If $P_{av}(j)$ is defined as the average probability of error for random codes when j errors are made in transmission, the following expression can be written for P_{av}:

$$P_{av} = \sum_{j=0}^{n} P_{av}(j) \binom{n}{j} p^j q^{n-j} \tag{5}$$

since

$$\binom{n}{j} q^j q^{n-j}$$

is the probability of j errors. To simplify equation 5, Elias obtains the following upper bounds for $P_{av}(j)$

$$P_{av}(j) \leq \frac{\sum_{i=0}^{j} \binom{n}{i}}{2^{n-k}} \leq \frac{\binom{n}{j}}{\binom{n}{k_1-1}} \text{ for } j \leq k_1 - 1$$

$$P_{av}(j) \leq 1 \text{ for } j \geq k_1$$

The expression for P_{av} now becomes

$$P_{av} < P_{av}' = \sum_{j=k_1}^{n} \binom{n}{j} p^j q^{n-j} + \sum_{i=0}^{k_1-1} \frac{\sum_{i=0}^{j} \binom{n}{j}}{2^{n-k}} \binom{n}{j} p^j q^{n-j} \tag{6}$$

$$P_{av}' \leq P_t + \sum_{j=0}^{k_1-1} \frac{\binom{n}{j}^2}{\binom{n}{k_1-1}} p^j q^{n-j} \tag{7}$$

The symbol P_{av}' is introduced only to have an easy reference to equation 6. Finally, Elias defines p_c and q_c which are functions of p and q:

$$p_c = \frac{\sqrt{p}}{\sqrt{p} + \sqrt{q}} \qquad q_c = \frac{\sqrt{q}}{\sqrt{p} + \sqrt{q}}$$

and obtains the following two bounds for P_{av}': if $p_1 < p_c$

$$P_{av}' < P_t^{ub} + \frac{p_1 q}{q_1 p \left[1 - \left(\frac{p_1}{q_1}\right)^2 \frac{q}{p}\right] \sqrt{2\pi n p_1 q_1}} \times 2^{-n[H(p) - H(p_1) + (p_1 - p) \log q/p]} \tag{8}$$

and if $p_1 > p_c$,

$$P_{av}' \leq p_t^{ub} + \frac{\left(q_1 + \frac{1}{n}\right)\sqrt{2np_1q_1}}{\pi p_c q_c} \times 2^{-n[H(p) + H(p_1) - 2H(p_c) + (p_c - p) \log q/p]} \tag{9}$$

where P_t^{ub} is the upper bound (equation 4) for P_t. The preceding expressions (equations 6, 8, and 9) for P_{av}' are for average of all codes. Elias[3,4] proves that the same expressions for P_{av}' are also valid for average of all parity check codes. However, the P_{av} for all codes may differ from the P_{av} for parity check codes, since P_{av}' is only an upper bound for P_{av}.

THE UPPER BOUND P_g

Gilbert[10] has discussed a lower bound for the maximum number of n-symbol binary sequences for which every pair differs in at least d positions. His argument can be rephrased to show that there is a set of 2^k n-digit sequences every pair of which differs in at least d positions, where d is the integer satisfying

Vol.
Pt. 1
195

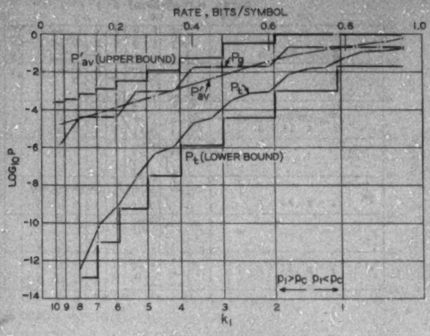

Fig. 2. Bounds for n=20, p=0.01

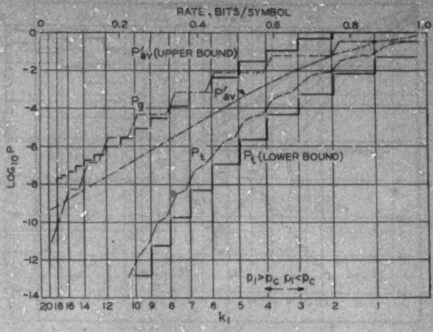

Fig. 4. Bounds for n=40, p=0.01

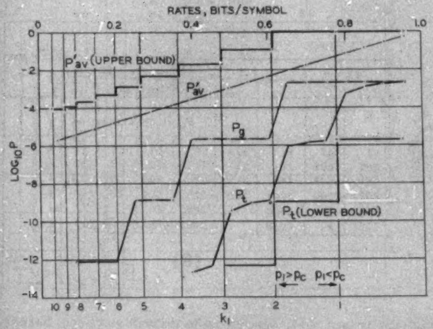

Fig. 3. Bounds for n=20, p=0.0001

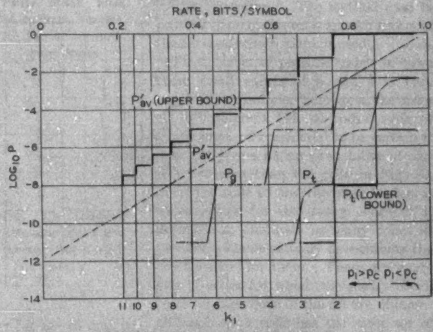

Fig. 5. Bounds for n=40, p=0.0001

$$2^k\sum_{j=1}^{d}\binom{n}{j} > 2^n \geq 2^k\sum_{j=0}^{d-1}\binom{n}{j}$$

If every pair of the 2^k code points differs in at least d positions, it is possible to correct all error patterns with fewer than $d/2$ errors. Thus, Gilbert's argument provides an upper bound for the probability of error which will be called P_g:

$$P_g = 1-\sum_{j=0}^{k_2}\binom{n}{j}p^jq^{n-j} \tag{10}$$

where k_2 is the integer satisfying $k_2 < d/2 \leq k_2+1$. Elias in his unpublished paper, "Coding for Two Noisy Channels," has noted that Gilbert's bound applies to parity check codes as well as nonparity check block codes so that $P_{opt} \leq P_g$.

CALCULATED RESULTS

In this section the exact expression for P_t (equation 1) will be compared with Elias' lower bound for P_t (equation 3). Also the exact expression for P_{av}' (equation 6) will be compared with Elias' upper bound for P_{av}' (equations 8 and 9) and with P_g (equation 10).

In Figs. 2–9, the logarithm of the probability of error for the various bounds is plotted as a function of rate for values of n equal to 20, 40, 80, and 160 and values of p equal to 0.01 and 0.0001.

The equations for P_t, P_{av}', and P_g are evaluated for integral values of k. Strictly speaking, this gives a series of points at the values of rate equal to k/n; but to indicate which points belong to which bound, the points are connected by straight lines. For n equal to 20 and 40, all the points are shown. For n equal to 80 and 160, the only points shown are the ones for which there is an abrupt change in the value of the equation. The omitted points lie either on or very close to the straight line segments.

Since k_1 and not k enters directly in equations 3, 8, and 9, it is convenient to evaluate them using integral values of k_1.

The rate R can then be calculated from equation 2 as:

$$R = k/n = 1-\frac{1}{n}\log\sum_{j=0}^{k_1}\binom{n}{j} \tag{11}$$

In most instances this does not give a value for the rate for which nR and hence k is an integer, but an evaluation of equation 3 at this value of rate provides a lower bound for P_{opt} for all rates larger than this. Similarly, evaluating equations 8 or 9 for a given k_1 and computing the corresponding rate from equation 11 gives an upper bound for P_{opt} for all rates less than this amount. The values of k_1 are shown in the figures. Also indicated are the values of k_1 for which $p_1 = k_1/n < p_c$ and for which $p_1 > p_c$.

DISCUSSION

Several observations can be made from the figures. For the most part, P_{av}' and P_t differ by several orders of magnitude for these small block lengths. The calculated values of P_{av}' and P_{av}' (upper bound) differ by a factor of ten or more, with P_{av}' the smaller. The calculated values for P_t are one or two orders of magnitude larger than P_t (lower bound) and this difference does not depend strongly on the rate but becomes smaller as n increases. For $p=0.0001$, P_g is a better upper bound than P_{av} for most values of rate except when $n=160$.

It is interesting that many of Elias' conclusions regarding the bounds for large n are applicable for these small values of n, and that when the curves are interpreted using the k_1 scale, Elias' conclusions are still substantially correct for these small values of n. For example, one of Elias' observations was that P_{av}' and P_t have the same exponent for $p_1<p_c$ and their ratio approaches a constant for large n. The curves for $p=0.01$ in the region for which $p_1<p_c$ exhibit this same property. Another conclusion was that as $p_1 \rightarrow p$, which is the same as the rate approaching the channel capacity, the ratio of the asymptotic expressions for P_{av}' and P_t approaches unity. The ratio of P_{av}' to P_t is nearly unity as $p_1 \rightarrow p$ for the curves that are shown, provided np_c is larger than one or two. If np_c is less than one, P_{av}' remains one or two orders of magnitude larger than P_t as $p_1 \rightarrow p$. For large n, random coding is as good as any coding scheme for rates approaching channel capacity. The figures show that this is not necessarily true for the bounds when n is small although it may be true for the actual codes. Finally, Elias concludes that for any $p_1<p_c$, random coding is very nearly as good as anything else, while for very low rates and sufficiently large n, P_g will be a lower upper bound than P_{av}'. These statements still hold for small n.

Evaluation of Actual Codes on the 704

DISCUSSION OF THE 704 PROGRAM

The operation of the program is based on two properties of the parity check sequence. The parity check sequence for a given received sequence is an $n-k$ symbol sequence of zeros and ones obtained as follows: The parity checks for the received sequence are calculated by using the information digits in that sequence. If the parity check computed from the received information symbols agrees with the corresponding parity check digit in the received sequence, a zero is written for the corresponding digit in the parity check sequence. If the two parity check symbols disagree, a one is written. Slepian

$$\begin{array}{c|cccccccc} & y_1 & y_2 & y_3 & y_4 & y_5 & y_6 & y_7 & y_8 \\ x_1 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 1 \\ x_2 & 1 & 0 & 0 & 1 & 1 & 0 & 1 & 1 \\ x_3 & 0 & 1 & 0 & 1 & 0 & 1 & 1 & 0 \\ x_4 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 \end{array} \qquad n = 12,\ k = 4$$

$$\begin{array}{ccccccccc} 1 & 1 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 \end{array} \qquad n = 13,\ k = 4$$

(B)

Fig. 10 (left). (A) Parity check rules of optimum codes. (B) The α's for optimum codes

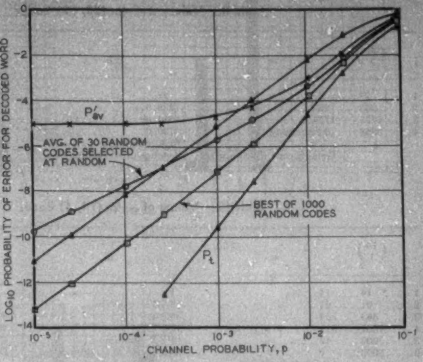

Fig. 11 (above). Random codes and bounds for $n=36$, $k=19$

showed that every member of a coset has the same parity check sequence and that no two cosets have the same parity check sequence.[2]

Given the parity check rules for the code, the program finds the 2^{n-k} coset leaders by trial and error. All sequences of weight one are tried first as proposed coset leaders. Then all sequences of weight two are considered and so forth. The parity check sequence is computed for each new proposed leader. If the parity check sequence has been used previously, the proposed leader cannot be used since it is in a coset whose leader was found previously. Otherwise, the proposed leader can be listed as a coset leader and its parity check sequence recorded. Since the weights of the successive proposed coset leaders increase monotonically, no element of a coset has smaller weight than the leader of that coset.

There are actually two programs. The first requires that $n \leq 36$ and $n-k \leq 20$ and the second that $37 \leq n \leq 72$ and $n-k \leq 20$. The first tests approximately 16,000 possible leaders per minute for $n=36$ and is somewhat faster for smaller n. The coset leaders with weight four or less can be found for a $n=14$, $k=4$ (14, 4) code in four seconds and for a $n=36$, $k=19$ (36, 19) code in four minutes. To get an adequate estimate of the probability of correct decoding for codes within the range of the program, it is usually not necessary to find the number of coset leaders with weight greater than four or five. The evaluation can be stopped after all sequences of an arbitrary weight are tried, thereby saving considerable machine time.

Application to Finding New Optimum Group Codes

Using this program we have extended Slepian's table by proving that the codes whose parity check rules are shown in Fig. 10 are optimum codes for $k=4$ and $n=12$, 13, 14, and 15. In Fig. 10(B), α_i is the number of error patterns with exactly i errors in them that a code will correct. Thus α_i is the number of coset leaders containing exactly i ones. These codes were constructed according to MacDonald's coding procedure.[9] The method used in proving them optimum is an adaptation of the method which Slepian used.

The number of possible codes for even these small values of n and k is very large. For example, there are in the order of 10^{12} different (14, 4) codes, each of which must be considered to be certain it does not give a higher probability of correct decoding than the code in Fig. 10. Since the time to find the coset leaders is unreasonable for this many codes, it is desirable to eliminate as many codes as possible without actually determining the coset leaders for them. There are many sets of codes for which the parity check rules for each code of the set are different although each code has the same set of α_i's. The *704* program was written to test at least one code while ignoring many, but not necessarily all, of the remaining codes in every such set. Secondly, the weights of the code points for a given code can be computed in a fraction of the time required to evaluate the code. It is possible to find a lower bound for the weight of all code points of any code that is better than the assumed optimum. Thus by computing the minimum weight of the code points and comparing it with the lower bound for the minimum weight, it was possible to eliminate many codes

Table I. Values of α_i for (36, 19) Codes

		(0 remaining) optimum		

without actually finding their α_i's. For the (14, 4) code this left 5,465 codes for which the α_i's had to be found. Approximately $5^1/_2$ hours of *704* machine time was needed to prove the (14, 4) code, shown in Fig. 10, to be optimum.

APPLICATION TO RANDOM CODES

Another application for the code evaluation program is random group codes. Several questions of interest concerning random codes are: 1. How conservative is the upper bound P_{av}' obtained in the section on "Bounds on the Probability of Error," compared to the actual average performance of random codes? 2. How good a code can be obtained by taking the best of several codes selected at random? and 3. How are random codes distributed about the average? In this section we shall present some experimental data pertinent to these questions.

The random codes were generated by using pseudo-random numbers to determine parity check rules. The actual procedure[11] was to use the $n-k$ high-order digits of the binary representation of successive powers of 5^{13} mod 2^{35}. One such set of digits is used for each of the k information digits: a one in the ith position in the $n-k$ random digits is taken to mean that the ith parity check includes the information digit in question.

Thirty random (36, 19) codes were generated and each evaluated to find the α_i's from α_0 through α_4. This left some coset leaders undetermined. The probability of error for the decoded word is

$$P=1-\sum_{i=0}^{n}\alpha_i p^i q^{n-i}$$

An upper bound on this probability can be found by neglecting coset leaders with weight greater than four. A lower bound is obtained by considering that all coset leaders with weight greater than four have weight five. Since for values of p equal to 0.1 or less these two bounds would be indistinguishable in Fig. 11 if both were plotted, the coset leaders with weight greater than four were not determined. The polynomial for the probability of error is linear in the α_i's. Therefore, the average probability of error for the 30 codes can be obtained by using the average values of the α_i's for the 30 codes. These average values are tabulated in Table I. In Fig. 11, the probability of error for the decoded word for the average of the 30 random codes is plotted against the probability of error for the channel. Also plotted are the P_g, P_t, and P_{av}' bounds. The probability of error for the decoded word for the average of these 30 codes is always less than P_{av}', which is to be expected, since P_{av}' is an upper bound for the average probability of error for random codes. P_{av} is a good upper bound for the probability of error for random codes at large values of p but a poor upper bound for small values of p. This would indicate that the average probability of error for random codes for the conditions of Fig. 5, for example, is much closer to P_t than P_{av} indicates. It is known from theory that P_g is a better bound than P_{av} for low rates. It is interesting to note that at low values of p, P_g is also a better bound than the average of the 30 codes. This might be expected, since for very low channel probability of error, the best code has a maximum minimum distance. Gilbert's bound is based on an estimate of minimum distance, but random codes would not in general be expected to have a large minimum distance.

To see how good a code can be obtained by generating random codes and selecting

the best, 1,000 random (36, 19) codes were generated and evaluated. The code that would correct all the single and double errors and the most triple errors was considered best. This gave a code considerably better than the average as shown by the α_i's tabulated in Table I and the probability of error for the decoded word plotted in Fig. 11. The curve for this best random code lies midway between the curves for the average of 30 codes and P_t and provides a good upper bound for the optimum (36, 19) parity check code. The optimum (36, 19) parity check code is not known and probably does not achieve the bound P_t, so that the best of the 1,000 random codes may be even closer to P_{opt} than is indicated by its nearness to P_t.

Except for Hamming's codes, Golay's "lossless" (23, 12) code is the largest known optimum code. Since this code corrects all single, double, and triple errors and no others, it achieves the bound P_t. To see how good the best of several random codes was in comparison with Golay's code, 3,000 (23, 12) random codes were generated and evaluated. The α_i's for the best code of these 3,000 are tabulated in Table II, and the probability of error for the decoded word is plotted in Fig. 12. Although the best of 3,000 random codes is much better than the bounds P_{av}' and P_g, it is considerably poorer than Golay's code.

Most optimum codes are not lossless codes, and optimum codes for many combinations of n and k do not achieve the lower bound P_t. To see how random coding compares with an optimum code which does not achieve P_t, several (14, 4) random codes were generated and evaluated. The α_i's for the average of 25 (14, 4) random codes selected at random and for the best of 2,000 (14, 4) random codes are tabulated in Table III. The code that corrected all the single- and double-error patterns and the most triples was considered best. The probability of error for the average of the 25 codes, for the best of the 2,000 codes, and for the optimum (14, 4) code together with the bounds are shown as functions of the channel probability in Fig. 13. The optimum (14, 4) code differs from the nonexistant hypothetical code represented by P_t in that the optimum code corrects 43 fewer quadruple-error patterns; instead it corrects 42 quintuple and one sextuple patterns. This has very little effect on the probability of error for the decoded word as is shown in Fig. 13. The best of 2,000 random codes is considerably better than the average of the 25 random codes and the bound P_g. It is interesting that for a given value of channel probability the best (14, 4) and (23, 12) random codes that were found differ from the optimum code by approximately the same amount.

In addition to being used to find a good code for a given n and k, random codes can also be used to find codes which will correct certain error patterns. For example, suppose that it is desirable to have a code that corrects all error patterns with one and two errors in them and at least all error patterns with triple errors that are in adjacent digit positions. The parity checks and the α_i's for a (28, 16) code that does this are shown in Fig. 14. The code was found by generating several random codes and saving only those that corrected all single- and double-error patterns. These were then evaluated to find out how many triple-error patterns were corrected. The evaluation program was modified to try next the 26 adjacent triple-error patterns as coset leaders. If the code were unable to correct one of these, the program tried to find a rearrangement of the symbols in the code points that would allow the triple-error pattern to be corrected. This of course does not affect the α_i's for a code, provided the symbols for each code point are rearranged in the same way.

The third area concerning random codes that was investigated was the distribution of the random codes about the average for several random codes. Shannon has noted that since the average of all random codes is good, most random codes are good codes. This is based on the fact that, if the average of n nonnegative numbers is X, then at most a fraction, $1/f$, of them can be larger than fX. The probability of error for the decoded word was calculated for each of the 30 (36, 19) random codes for three values of channel probability (0.01, 0.00025, 0.00001). The distribution of the probability of error for the 30 codes is shown as a frequency bargraph in Fig. 15. Also shown are the bounds P_{av}, P_g, P_t, and the probability of error for the best of 1,000 random codes. From the preceding, there could be at most 3 of the 30 codes that have a probability of error ten times larger than the average. Actually, there are none. However, for $p=10^{-5}$ there are 18 of the codes that have a probability of error two or three orders of magnitude smaller than the average, and of these the best is nearly equal to the best of 1,000. Thus, the best of 20 or 30 random codes selected at random is a good code and it appears that the improvement gained in using a larger number than this is small unless, perhaps the number is very large.

Fig. 15 illustrates again that for small values of channel probability, the minimum distance between all pairs of code points is an important factor in determining the probability of error for a code. The 18 best codes shown in Fig. 15 correct all 630 double but not all triple-error patterns and hence each has a minimum distance of 5 or 6. The remaining 12 codes correct all the single-error patterns and from 621 to 627 of the double-error patterns, so that the minimum distance for these codes is 3 or 4.

Conclusions

Upper and lower bounds on error probability of medium length binary codes found by Elias and Gilbert were studied. The bounds have the same general characteristics for these block lengths as the theory indicates they have for large n. However, they may differ by several orders of magnitude for small n.

Codes of medium length were also studied by means of evaluation of error probability on the IBM *704* computer. Several new codes have been proved optimum. In addition studies of random codes were made. It was found that the upper bound for the average probability of error for all random codes may be three or four orders of magnitude larger than the actual average for random codes for small p. It was also observed that good codes can be obtained by generating and evaluating several random codes and selecting the best of these. In the cases investigated, there was little advantage in generating more than 20 or 30 codes to obtain a good one. Although it is easy to obtain a good code using random codes, the best random codes in 3,000 (23, 12) and 2,000 (14, 4) codes were not as good as the optimum for these values. Finally, it was possible to use random codes to obtain codes which correct certain specific error patterns.

Discussion

The following closure includes a number of oral comments by Professor P. Elias on the paper and the authors' reply to them.

A. B. Fontaine and W. W. Peterson: Prof. Elias pointed out to us that the expression P_{av}' is greater than P_{av}, the average probability of error or ambiguity for all block codes, by no more than about 60%. An exact expression for $P_{av}(j)$ is:

$$P_{av}(j) = 1 - \left[1 - 2^{-n}\sum_{i=0}^{j}\binom{n}{i}\right]^{2^k-1} \tag{12}$$

The "well-known inequality" $1-(1-x)^y \leqq xy$ is then applied to give

$$P_{av}(j) \leqq \frac{2^k-1}{2^n}\sum_{i=0}^{j}\binom{n}{i} \tag{13}$$

or 1, whichever is smaller. The greatest difference in terms of percentage occurs when the right-hand side of equation 13 is unity, and that can easily be shown to be less than $e/(e-1)=1.582$. Dropping the one in the factor 2^k-1 increases the right-hand side by one part in 2^k, which is usually negligible.

Elias has shown that P_{av}' is an upper bound on the average probability of error for all parity-check codes. However, more approximations are involved, so that P_{av}' is not a close upper bound for small channel probability of error p. In fact, the worst possible parity-check code is the code in which the parity checks check no information places, and it has the same probability of error as if there were no parity checks at all, i.e., $1-(1-p)^k$. This approaches zero (approximately as kp) as p approaches zero while P_{av}' approaches $2^{-(n-k)}$. A closer bound on the average probability of error for all parity check codes, derived below, is

$$P_{av}'' = 2^{-(n-k)}\sum_{j=1}^{n} p^j q^{n-j}\left[\binom{n}{j}\sum_{i=0}^{j}\binom{n}{i} - \sum_{r=0}^{j}\sum_{i=0}^{j}\binom{n-k}{j-r}\binom{n-k}{i-r}\binom{k}{r}\right] \tag{14}$$

As p approaches zero, all terms beyond the first in equation 14 become negligible, and

$$P_{av}'' \approx 2^{-(n-k)}kp(2n-k) \tag{15}$$

It can be shown that the correct value of the leading term in the average probability of error or ambiguity for all parity-check codes is

$$2^{-(n-k)}kp[2n-k-2^{-(n-k)}(k-1)(n-k+1)] \tag{16}$$

which differs very little from equation 15 unless $n-k$ is very small.

When compared to the observed average for the samples of 20 or 30 random (23, 12) and (36, 19) codes, the discrepancies are much greater than this. Elias suggested the following explanation: There are not many very bad codes, but they may contribute a great deal to the average probability of error, because their probability of error (for small p) may be several orders of magnitude greater than the average. A small sample is not likely to include one of these, and therefore, has a high probability of having a sample average smaller than actual average. In short, the distribution of probability of error is so skew that the distribution of sample average is also very skew.

The upper bound on average probability of error for parity-check codes will be derived assuming the reader familiar with the theory of group codes.[1] A parity-check code can be described by giving its generators in the form of an $n \times k$ matrix of ones and zeros. The first k columns at the left are called the information places, and in the $n \times k$ matrix they form a $k \times k$ identity matrix. The remaining $n-k$ columns are parity-check columns, and the configuration of ones and zeros determines the parity-check rules. Each of the $2^{k(n-k)}$ ways of filling ones and zeros in these $k(n-k)$ positions describes a different parity-check code, though many differ in trivial ways. An upper bound is desired for the average probability of error for all these codes, weighting them equally.

As a first step, the number of codes containing a given n-bit sequence as a code word is required. If the n-bit sequence has all zeros in the information places, but does not have all zeros in the parity-check places, it cannot be a code word in any code. If, however, it does not have all zeros in the information places, then there are $2^{(k-1)(n-k)}$ codes containing this word. This can be seen as follows: if the given sequence has more than a single one in the information places, generators should be added (bit by bit, modulo 2) until there is only a single bit left in the information places. The n-bit sequence derived in this manner is a code word if, and only if, the original sequence was. Since it has only a single one in the information places, it must be a generator. The other $k-1$ generators are arbitrary, but once they are chosen this last generator is also determined. Thus, $(k-1)(n-k)$ bits can be chosen freely, and $2^{(k-1)(n-k)}$ codes constructed which contain the given word as a code word.

Now consider an error pattern which has j ones of which r are in the information places. This error pattern will result in ambiguity or erroneous decoding if there is any sequence containing $i \leq j$ ones such that the sum of the error pattern and the other sequence is a code point. This will happen for $2^{(k-1)(n-k)}$ codes if the sum has any ones in the information places, but for no codes if the sum has no ones in information places. There are $\binom{n}{i}$ sequences containing i ones, of which $\binom{n-k}{i-r}$ have information places identical with those in the error pattern, and hence when added to the error pattern results in a sequence with all zeros in the information places. This leaves $\binom{n}{i}-\binom{n-k}{i-r}$ sequences with i ones for which the sum does not have all zeros in the information places. Therefore, there are at most

$$2^{(k-1)(n-k)}\sum_{i=1}^{j}\left[\binom{n}{i}-\binom{n-k}{i-r}\right] \qquad (17)$$

codes out of the total of $2^{k(n-k)}$ which fail to correct a particular error pattern with j errors of which r are in information places. The probability of choosing a code at random which will fail to correctly decode such an error pattern is less than or equal to

$$P(j,r)=\sum_{i=0}^{j}\left[\binom{n}{i}-\binom{n-k}{i-r}\right]2^{-(n-k)} \qquad (18)$$

Each error pattern of this kind has probability $p^j q^{n-j}$ and there are $\binom{k}{r}\binom{n-k}{j-r}$ of them. Summing over j and r gives the over-all bound on average probability of error

$$P_{av}'=\sum_{j=0}^{n}\sum_{r=0}^{j}P(j,r)\binom{k}{r}\binom{n-k}{j-r}p^j q^{n-j}$$

$$=\sum_{j=0}^{n}\sum_{r=0}^{j}\sum_{i=0}^{j}p^j q^{n-j}\binom{k}{r}\binom{n-k}{j-r}\times \left[\binom{n}{i}-\binom{n-k}{i-r}\right]2^{-(n-k)}$$

$$=2^{-(n-k)}\sum_{j=0}^{n}p^j q^{n-j}\left[\binom{n}{j}\sum_{i=0}^{j}\binom{n}{j}-\sum_{r=0}^{j}\sum_{i=0}^{j}\binom{n-k}{j-r}\binom{n-k}{i-r}\binom{k}{r}\right] \qquad (19)$$

The term for which $j=0$ vanishes, yielding equation 14. This can be refined somewhat by noting $P(j,r)$ is an upper bound on a probability and hence can be replaced by 1 if it is greater than 1. If this is done and if the negative terms in $P(j,r)$ are dropped, the expression for P_{av}' results.

L. J. RINDT
NONMEMBER AIEE

A COMPLETE matrix of self and mutual drops, with respect to a single reference point, will completely describe the constraints of a network as far as the significant points are concerned. Thus, these drops are a useful tool in the solution of network problems and have long been recognized as such. Previous to the days of the a-c network calculator, they were in widespread use for the calculation of losses, regulation short-circuit currents, etc. With the advent of the loss formula,[1] these drops assumed a new role. Ironically the a-c network calculator, which once subjugated these drops to a relatively minor role, now permitted their economical use by providing a means of obtaining them by direct measurement. For some time now the network calculator has been used quite widely to determine these drops; however, this method still involved considerable time and patience, and there was a serious question as to whether the accuracy obtained was sufficient for all purposes.

These limitations prompted an investigation as to the feasibility of obtaining these drops using a digital computer. The result of this investigation was a digital program that calculated the self and mutual drops of a system with a high degree of accuracy and at the same time compared favorably with the a-c network calculator method cost. A natural by-product of this digital program was the elimination of the tedious labor involved in the other methods and the reduction of a-c network calculator time required for obtaining a loss formula.

During the course of use of this particular digital program, the problem of obtaining these drops for a large system as well as those for its subsystems arose. Although the same program could be used for each of the various systems, a possibility existed that the self and mutual drops of the various subsystems could be modified and combined to form the self and mutual drops of the entire system. The investigation of this problem led to a digital program which would combine the self and mutual drops of two or more systems to form the drops

Paper 58-890, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, New York, June 22–27, 1958. Manuscript submitted March 14, 1958; made available for printing April 28, 1958.

R. W. Ferguson, R. W. Long, and L. J. Rindt are with Westinghouse Electric Corporation, East Pittsburgh, Pa.

for the system composed of the combination of these subsystems. A ramification of this program is the inclusion of a new line or group of lines into the matrix of self and mutual drops for a basic system.

This paper considers the theoretical background of the afore-mentioned two digital programs. Since the heart of the digital program that is used to obtain the self and mutual drops from the system impedances is commonly used in digital calculations, no attempt will be made to show the details of the program. However, a block diagram of the digital program for combining self and mutual drops is included.

Obtaining Self and Mutual Drops from the System Impedances

The matrix of self and mutual drops as considered here will be a square symmetrical matrix with the number of rows and columns equal to one less than the number of busses of the system which it describes. Any term in the matrix may be defined as follows:

D_{nn} = the voltage drop from the reference bus to bus *n* with one per unit current entering the system at the reference bus and leaving at bus *n*

D_{nm} = the voltage drop from the reference bus to bus *m* with one per unit current entering the system at the reference bus and leaving at bus *n*

Having defined the objective, an analysis of the method of obtaining it follows.

Consider the sample network shown in Fig. 1, consisting of three busses and three lines. The currents I_2 and I_3 are considered as flowing out of the network, while I_1 is considered as flowing into the network. Bus *1* will be designated as the reference bus.

Kirchhoff's law states that the vector sum of all the currents flowing to any bus is equal to zero. Using this law and expressing the currents within a network in terms of the bus voltages and line admittances, equations can be written describing the currents entering and leaving the network. Equations 1, 2, and 3 describe these currents for the sample network.

$$(E_1-E_2)y_{1-2}+(E_1-E_3)y_{1-3}=I_1 \qquad (1)$$

$$(E_1-E_2)y_{1-2}+(E_3-E_2)y_{2-3}=I_2 \qquad (2)$$

$$(E_1-E_3)y_{1-3}-(E_3-E_2)y_{2-3}=I_3 \qquad (3)$$

Rearranging the terms of equations 1, 2, and 3 the familiar form of the nodal equation is

$$E_1(y_{1-2}+y_{1-3})+E_2(-y_{1-2})+E_3(-y_{1-3})=I_1 \qquad (4)$$

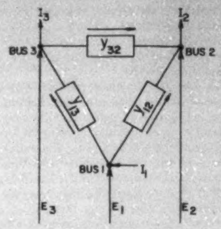

Fig. 1. Simple network showing pertinent parameters

$$E_1(-y_{1-2})+E_2(y_{1-2}+y_{2-3})+E_3(-y_{2-3})=-I_2 \qquad (5)$$

$$E_1(-y_{1-3})+E_2(-y_{2-3})+E_3(y_{1-3}+y_{2-3})=-I_3 \qquad (6)$$

These equations express the fact that the currents flowing into the network at a bus are equal to the sum of the products of *Ey*, where the self-admittance term, or the diagonal admittance of the particular row of a matrix, is obtained by summing the mutual admittance, or off diagonal terms, while the remaining *y*'s are the line admittance terms involved with their sign changed.

Since the self and mutual drops concern themselves with voltage drops from the reference bus, and since bus *1* is designated as the reference bus in the sample system, the voltage at bus *1* is the reference voltage. This means that the reference voltage may be written as equal to the voltage at bus *1* as in equation 7, and the voltage drops from the reference bus to bus *2* and *3* as in equations 8 and 9, respectively.

$$E_R=E_1 \qquad (7)$$

$$V_2=E_R-E_2 \qquad (8)$$

$$V_3=E_R-E_3 \qquad (9)$$

Combining equations 4 through 9 results in

$$E_R(y_{1-2}+y_{1-3})+(E_R-V_2)(-y_{1-2})+(E_R-V_3)(-y_{1-3})=I_1 \qquad (10)$$

$$E_R(-y_{1-2})+(E_R-V_2)(y_{1-2}+y_{2-3})+(E_R-V_3)(-y_{2-3})=-I_2 \qquad (11)$$

$$E_R(-y_{1-3})+(E_R-V_2)(-y_{2-3})+(E_R-V_3)(y_{1-3}+y_{2-3})=-I_3 \qquad (12)$$

An examination of these equations shows that all of the E_R terms drop out and the resultant equations appear as

$$V_2(-y_{1-2})+V_3(-y_{1-3})=-I_1 \qquad (13)$$

$$V_2(y_{1-2}+y_{2-3})+V_3(-y_{2-3})=I_2 \qquad (14)$$

$$V_2(-y_{2-3})+V_3(y_{1-3}+y_{2-3})=I_3 \qquad (15)$$

Since the sum of the currents into the network must equal the sum of the currents out of the network,

$$I_1=I_2+I_3 \qquad (16)$$

With this relationship established, equation 13 can be eliminated, since equations 13, 14, and 15 do not form a group of independent equations. A further simplification can be made by recognizing that the admittance terms are of the form of driving point and transfer admittances.[3] Thus, equations 14 and 15 can be rewritten as

$$V_2Y_{22}+V_3Y_{23}=I_2 \qquad (17)$$

$$V_2Y_{23}+V_3Y_{33}=I_3 \qquad (18)$$

These equations may then be solved to obtain the voltage drops from the reference bus (V_2 and V_3) in terms of the driving point and transfer admittances and the currents I_2 and I_3.

Now reconsider the definitions previously stated for D_{nn} and D_{nm} and write the equations to fit these definitions. First, if a unit current enters at bus *1* and leaves at bus *2*, $I_2=1$ and $I_3=0$. Then $D_{22}=V_2$ and $D_{23}=V_3$ can be obtained from the solution of

$$V_2Y_{22}+V_3Y_{23}=1 \qquad (19)$$

$$V_2Y_{23}+V_3Y_{33}=0 \qquad (20)$$

If a unit current is now allowed to enter at bus *1* and leave at bus *3*, $I_2=0$ and $I_3=1$. $D_{33}=V_3$ and $D_{32}=V_2$ can then be obtained from the solution of

$$V_2Y_{22}+V_3Y_{23}=0 \qquad (21)$$

$$V_2Y_{23}+V_3Y_{33}=1 \qquad (22)$$

The solution of these two sets of equations are readily seen to involve just those operations which one uses to find the inverse of a matrix. That is, both sets may be solved at the same time by considering the problem of finding the *D*'s in the matrix equation 23, which is expressed in equations 19 through 22 in matrix form, recognizing that the voltage drops represent the self and mutual drops.

$$\left\|\begin{matrix}D_{22}D_{23}\\D_{32}D_{33}\end{matrix}\right\|\cdot\left\|\begin{matrix}Y_{22}Y_{23}\\Y_{23}Y_{33}\end{matrix}\right\|=\left\|\begin{matrix}1&0\\0&1\end{matrix}\right\| \qquad (23)$$

Thus the conclusion that the self and mutual drop matrix (*D* matrix) is just the inverse of the driving point and transfer admittance matrix (*Y* matrix) with its first row and column deleted.

Digital Program

This is the problem that has been programmed for the IBM *704*. Each bus of a given power system is numbered in order, making sure that the reference bus is assigned *1*. All lines connected to bus *1* are listed with its impedances and then

Table I. Form for Tabulating Input Data*

Row	Column	Real Impedance	Imaginary Impedance

* Used for program which calculates self and mutual drops.

Table II. Typical Times for Inverting Admittance Matrix

Number of Busses	Time in Minutes
22	5
48	25
81	63

all those not already listed which are connected to bus *2*, etc. In Fig. 1 they would be listed as shown in Table I. Each row of this table would represent the information punched on one card. These cards are fed into the computer along with a card denoting the number of busses and lines. The program automatically proceeds to form the driving point and transfer admittance matrix; then deletes its first row and column; and inverts the matrix.

The program as outlined here is a complex double-precision matrix inversion program and has been used successfully in inverting several different systems. Examples of the size of the matrix and the time for inversion is shown in Table II. Naturally these times reflect the fact that there are only a limited number of lines connected to any one bus and that they are applicable only to typical power system problems.

Combination of Self and Mutual Drop Matrices

The problem to be considered in this section is the development of the self and mutual drops for a system from the self and mutual drops for two or more subsystems which make up this system. These subsystems are connected together at certain tie points and it is upon this fact that the solution is developed.

ASSUMPTIONS

The equations to be developed are based on the following assumptions:

1. The reference bus in each subsystem is chosen so as not to coincide with any of the tie points between them.
2. When the tie points of a system are listed in ascending order of bus numbers, they will agree exactly with a similar list made using the bus numbers of these tie points in the connecting system. An example of this would be as follows: If busses *5*, *7*, and *10* are the tie points of one system and busses *8*, *12*, and *14* are the tie points of the connecting system, then busses *5* and *8*, *7* and *12*, and *10* and *14* should refer to the same points respectively.

Assumption 2 makes the bookkeeping in the problem a little easier and negates the necessity of interchanging certain columns and rows of the matrices involved.

NOMENCLATURE

Assume a power system made up of two subsystems which are represented as system *A* and system *B*. Such a system is shown in Fig. 2. Systems *A* and *B* are connected to each other at certain tie points. The self and mutual drops for the two systems are represented by the *D* matrices in the equations

$$\|E^A\| = \|D^A\| \cdot \|I^A\| \tag{24}$$

$$\|E^B\| = \|D^B\| \cdot \|I^B\| \tag{25}$$

where the superscript *A* and *B* are used to refer to the *A* and *B* systems respectively.

To clarify the nomenclature further, each bus will be defined as one of the following three types: (1) reference bus designated by subscript *R;* (2) tie bus designated by the subscript *T;* (3) all other designated by the subscript *G*. When these subscripts are used for matrices and submatrices, they designate all such rows and columns of a system matrix. Consider the self and mutual drop matrix for system *A*.

$$\left\|\begin{array}{llll} D_{11}{}^A & D_{12}{}^A & D_{13}{}^A \ldots\ldots\ldots & D_{1T}{}^A \\ & D_{1(T+1)}{}^A \ldots\ldots\ldots & D_{1N}{}^A & \\ D_{21}{}^A & D_{22}{}^A & D_{23}{}^A \ldots\ldots\ldots & D_{2T}{}^A \\ & D_{2(T+2)}{}^A \ldots\ldots\ldots & D_{2N}{}^A & \\ \vdots & & & \\ D_{T1}{}^A & D_{T2}{}^A & D_{T3}{}^A \ldots\ldots\ldots & D_{TT}{}^A \\ & D_{T(T+1)}{}^A \ldots\ldots\ldots & D_{TN}{}^A & \\ D_{(T+1)1}{}^A & D_{(T+1)2}{}^A & D_{(T+1)3}{}^A \ldots & D_{(T+1)T}{}^A \\ & D_{(T+1)T(T+1)}{}^A \ldots\ldots & D_{(T+1)N}{}^A & \\ \vdots & & & \\ D_{N1}{}^A & D_{N2}{}^A & D_{N3}{}^A \ldots\ldots\ldots & D_{NT}{}^A \\ & D_{N(T+1)}{}^A \ldots\ldots\ldots & D_{NN}{}^A & \end{array}\right\| \tag{26}$$

The subscript *T* is used to indicate those terms involving tie points. The submatrix, which is formed by those terms having *T* in both the column and row subscript, is designated by $D_{TT}{}^A$. To simplify the subscript nomenclature further, the subscript *P* will designate all the rows or columns of the self and mutual drop matrix. Thus the entire matrix of the self and mutual drops will be referred to as $D_{PP}{}^A$ and the complete tie column submatrix as $D_{PT}{}^A$. The submatrices $D_{PP}{}^A$, $D_{PT}{}^A$, and $D_{TT}{}^A$ are shown diagrammatically as in Figs. 3(A), 3(B), and 3(C), respectively. It is to be seen the matrix $D_{PP}{}^A$ contains all of the terms of $D_{PT}{}^A$ and $D_{TT}{}^A$ and that $D_{PT}{}^A$ contains all of the terms of $D_{TT}{}^A$. These matrices were purposely defined this way because each tie point will appear as a point in the combined system.

Since the tie points will only appear once in the combined system matrix and the *A* system matrices were defined to include them, the *B* system matrices will be defined without them. Thus $D_{GG}{}^B$, $D_{GT}{}^B$ and $D_{TT}{}^B$ are mutually exclusive and so have no terms in common. These three matrices are shown schematically in Fig. 4(A), 4(B), and 4(C) respectively.

The use of a single subscript will denote a column vector consisting of all the row terms that are designated by the subscripts. For example, $I_T{}^A$ is the column vector of the currents at the tie busses. $I_T{}^{A\prime}$ will have the customary meaning of being the transpose of $I_T{}^A$, which in this case would be a row vector with a similar definition. Another notation of this type would be $E_R{}^A - E_P{}^A$. This will be taken to mean the column vector of the voltage drops from the reference bus in the *A* system to all other busses in the *A* system. Similarly, $E_R{}^A - E_R{}^B$ will be taken as the voltage drop from the reference bus of the *A* system to the reference bus of the *B* system.

Lastly, it will be well to point out that all of the terms of the various matrices and submatrices are complex numbers and complex arithmetic is involved in these calculations. Submatrices designated as 1 and 0 are thus $1+JO$ and $0+JO$ respectively. While the 1 submatrices may be superscripted and subscripted in accordance with the notation above, the 0 submatrices will be assumed to have the proper number of rows and columns to make the matrices involved conformable.

DEVELOPMENT OF THE EQUATIONS

Using the preceding notation, matrix equations can be written for the *A* and *B* systems respectively

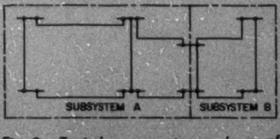

Fig. 2. Typical power system made up of two subsystems

$$\left\|\begin{array}{c} E_R{}^A-E_P{}^A \\ \hdashline E_R{}^A-E_T{}^A \end{array}\right\| = \left\|\begin{array}{c:c} D_{PP}{}^A & D_{PT}{}^A \\ \hdashline D_{TP}{}^A & D_{TT}{}^A \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_T{}^A \end{array}\right\| \qquad (27)$$

$$\left\|\begin{array}{c} E_R{}^B-E_G{}^B \\ \hdashline E_R{}^B-E_T{}^B \end{array}\right\| = \left\|\begin{array}{c:c} D_{GG}{}^B & D_{GT}{}^B \\ \hdashline D_{TG}{}^B & D_{TT}{}^B \end{array}\right\| \cdot \left\|\begin{array}{c} I_G{}^B \\ \hdashline I_T{}^B \end{array}\right\| \qquad (28)$$

In these two equations, it is understood that the various quantities $D_{PP}{}^A$, $I_P{}^A$, $E_R{}^B-E_G{}^B$, etc., are submatrices having the appropriate number of rows and columns.

Each term of the left hand matrix of equation 28 may be typically rewritten

$$(E_R{}^B-E_N{}^B)=(E_R{}^A-E_N{}^B)-(E_R{}^A-E_R{}^B) \qquad (29)$$

This permits equation 28 to be written

$$\left\|\begin{array}{c} E_R{}^A-E_G{}^B \\ \hdashline E_R{}^A-E_T{}^B \end{array}\right\| - (E_R{}^A-E_R{}^B)\left\|\begin{array}{c} 1_G{}^B \\ \hdashline 1_T{}^B \end{array}\right\| = \left\|\begin{array}{c:c} D_{GG}{}^B & D_{GT}{}^B \\ \hdashline D_{TG}{}^B & D_{TT}{}^B \end{array}\right\| \cdot \left\|\begin{array}{c} I_G{}^B \\ \hdashline I_T{}^B \end{array}\right\| \qquad (30)$$

Since the sum of all the currents entering and leaving system B must be equal to zero,

$$0=\left\|\begin{array}{c:c:c} 1_G{}^{B'} & 1_T{}^{B'} & 1 \end{array}\right\| \cdot \left\|\begin{array}{c} I_G{}^B \\ \hdashline I_T{}^B \\ \hdashline I_R{}^B \end{array}\right\| \qquad (31)$$

As each tie current in system B is the negative of this same current in system A,

$$\|I_T{}^B\|=\|-I_T{}^A\| \qquad (32)$$

This relationship may be substituted into equations 30 and 31 and they may be then combined to give

$$\left\|\begin{array}{c} E_R{}^A-E_G{}^B \\ \hdashline E_R{}^A-E_T{}^B \\ \hdashline E_R{}^A-E_R{}^B \end{array}\right\| - (E_R{}^A-E_R{}^B)\left\|\begin{array}{c} 1_G{}^B \\ \hdashline 1_T{}^B \\ \hdashline 1 \end{array}\right\| = \left\|\begin{array}{c:c:c} D_{GG}{}^B & D_{GT}{}^B & 0 \\ \hdashline D_{TG}{}^B & D_{TT}{}^B & 0 \\ \hdashline 1_G{}^{B'} & 1_T{}^{B'} & 1 \end{array}\right\| \cdot \left\|\begin{array}{c} I_G{}^B \\ \hdashline -I_T{}^A \\ \hdashline I_R{}^B \end{array}\right\| \qquad (33)$$

Consider the second row of equations 27 and 33. They are respectively

$$\|E_R{}^A-E_T{}^A\|=\left\|\begin{array}{c:c} D_{TP}{}^A & D_{TT}{}^A \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_T{}^A \end{array}\right\| \qquad (34)$$

$$\|E_R{}^A-E_T{}^B\|=(E_R{}^A-E_R{}^B)\|1_T{}^B\|+ \left\|\begin{array}{c:c:c} D_{TG}{}^B & D_{TT}{}^B & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_G{}^B \\ \hdashline -I_T{}^A \\ \hdashline I_R{}^B \end{array}\right\| \qquad (35)$$

Since the tie points in each system are identical points, when the systems are combined the voltages at the tie points of each system are the same. This gives

$$\|E_R{}^A-E_T{}^A\|=\|E_R{}^A-E_T{}^B\| \qquad (36)$$

Having this relationship, the right hand members of equations 34 and 35 may be equated

$$(E_R{}^A-E_R{}^B)\|1_T{}^B\|=\left\|\begin{array}{c:c} D_{TP}{}^A & D_{TT}{}^A \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_T{}^A \end{array}\right\| - \left\|\begin{array}{c:c:c} D_{TG}{}^B & D_{TT}{}^B & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_G{}^B \\ \hdashline -I_T{}^A \\ \hdashline I_R{}^B \end{array}\right\| \qquad (37)$$

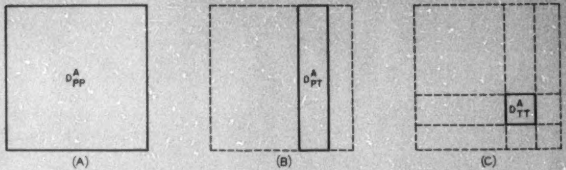

Fig. 3. Various submatrices of the A system's self and mutual drop matrix

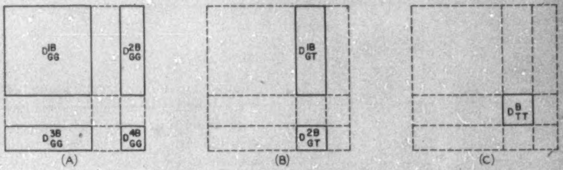

Fig. 4. Various submatrices of the B system's self and mutual drop matrix

$$\text{A}\text{—}D_{GG}{}^B=\left\|\begin{array}{c:c} D_{GG}{}^{1B} & D_{GG}{}^{2B} \\ \hdashline D_{GG}{}^{3B} & D_{GG}{}^{4B} \end{array}\right\|$$

$$\text{B}\text{—}D_{GT}{}^B=\left\|\begin{array}{c} D_{GT}{}^{1B} \\ \hdashline D_{GT}{}^{2B} \end{array}\right\|$$

Rearranging the terms in equation 37 results in

$$(E_R{}^A-E_R{}^B)\|1_T{}^B\|=\left\|\begin{array}{c:c:c} D_{TP}{}^A & -D_{TG}{}^B & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| + \|D_{TT}{}^A+D_{TT}{}^B\| \cdot \|I_T{}^A\| \qquad (38)$$

The third row of equation 33 can be rewritten as

$$0=\left\|\begin{array}{c:c:c} 0 & 1_G{}^{B'} & 1 \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| - \|1_T{}^{B'}\| \cdot \|I_T{}^A\| \qquad (39)$$

Although the form of equations 38 and 39 is not necessarily the simplest, the current matrix represents the form needed in the solution of the problem.

Since the number of ties is the same in each system, $1_T{}^B$ is the same as $1_T{}^A$. This enables the combining of equations 38 and 39 into

$$\left\|\begin{array}{c:c} -D_{TT}{}^A-D_{TT}{}^B & 1_T{}^A \\ \hdashline 1_T{}^{A'} & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_T{}^A \\ \hdashline E_R{}^A-E_R{}^B \end{array}\right\| = \left\|\begin{array}{c:c:c} D_{TP}{}^A & -D_{TG}{}^B & 0 \\ \hdashline 0 & 1_G{}^{B'} & 1 \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| \qquad (40)$$

The first matrix in equation 40 can be eliminated from the left hand side by multiplying both sides of the equations by the inverse of this matrix. If the product of the inverse matrix and the third matrix of equation 40 is designated as matrix C, then equation 40 can be written as

$$\left\|\begin{array}{c} I_T{}^A \\ \hdashline E_R{}^A-E_R{}^B \end{array}\right\| = \|C\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| \qquad (41)$$

Equation 41 will be substituted into the appropriate places of equations 27 and 33. That is, in the first row of equation 27 and also in the first and third row of equation 33. To make this process a little easier to visualize, these rows will be rewritten as equations 42, 43, and 44, respectively.

$$\|E_R{}^A-E_P{}^A\|=\left\|\begin{array}{c:c:c} D_{PP}{}^A & 0 & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| + \left\|\begin{array}{c:c} D_{PT}{}^A & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_T{}^A \\ \hdashline E_R{}^A-E_R{}^B \end{array}\right\| \qquad (42)$$

$$\|E_R{}^A-E_G{}^B\|=\left\|\begin{array}{c:c:c} 0 & D_{GG}{}^B & 0 \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| + \left\|\begin{array}{c:c} -D_{GT}{}^B & 1_G{}^B \end{array}\right\| \cdot \left\|\begin{array}{c} I_T{}^A \\ \hdashline E_R{}^A-E_R{}^B \end{array}\right\| \qquad (43)$$

$$\|E_R{}^A-E_R{}^B\|=\left\|\begin{array}{c:c:c} 0 & 1_G{}^{B'} & 1 \end{array}\right\| \cdot \left\|\begin{array}{c} I_P{}^A \\ \hdashline I_G{}^B \\ \hdashline I_R{}^B \end{array}\right\| + \left\|\begin{array}{c:c} -1_T{}^{A'} & 1 \end{array}\right\| \cdot \left\|\begin{array}{c} I_T{}^A \\ \hdashline E_R{}^A-E_R{}^B \end{array}\right\| \qquad (44)$$

By substituting equation 41 into equations 42, 43, and 44 and combining the three resultant equations into one matrix equation, an equation is produced which can be solved to obtain one row of the self and mutual drop matrix for the

Fig. 5 (left). Block diagram of program for combining the self and mutual drop matrix for system A and B. (Superscript and subscript notation is the same as used in the text)

combined A and B system. This equation is shown as

$$\left\| \begin{array}{c} E_R^A - E_P^A \\ \hdashline E_R^A - E_G^B \\ \hdashline E_R^A - E_R^B \end{array} \right\| = \left\{ \left\| \begin{array}{c:c:c} D_{PP}^A & 0 & 0 \\ \hdashline 0 & D_{GG}^A & 0 \\ \hdashline 0 & 1_G^{B'} & 1 \end{array} \right\| + \left\| \begin{array}{c:c} D_{PT}^A & 0 \\ \hdashline -D_{GT}^B & 1_G^B \\ \hdashline -1_T^{A'} & 1 \end{array} \right\| \cdot \|C\| \right\} \cdot \left\| \begin{array}{c} I_P^A \\ \hdashline I_G^B \\ \hdashline I_R^B \end{array} \right\| \quad (45)$$

To solve equation 45 for a complete matrix of self and mutual drops would require that it be solved for as many cases as there are rows in the current matrix. In each case all of the currents except one would be zero, the remaining current would be one. If all of the equations for these different cases were written as one matrix equation, then the current matrix would be a unit matrix of appropriate size and the resulting equation would be

$$\|D\| = \left\| \begin{array}{c:c:c} D_{PP}^A & 0 & 0 \\ \hdashline 0 & D_{GG}^B & 0 \\ \hdashline 0 & 1_G^{B'} & 1 \end{array} \right\| + \left\| \begin{array}{cc} D_{PT}^A & 0 \\ -D_{GT}^B & 1_G^B \\ -1_T^{A'} & 1 \end{array} \right\| \cdot \|C\| \quad (46)$$

where the D matrix is the self and mutual drop matrix for the system formed by combining system A and B.

It should be pointed out here that to solve equation 46 requires matrix multiplication and addition with one matrix inverse. The inverse of a matrix is used to determine matrix C. However, this is a small square matrix which size is equal to the number of tie points plus one.

Digital Program

An IBM *704* program has been written to solve equation 46. A general-type block diagram is shown in Fig. 5 illustrating the steps followed by the program in obtaining the combined matrix of self and mutual drop matrix for an over-all system from self and mutual drop matrix of two systems which combined form the over-all system.

This program has been applied to systems of 37 and 94 busses respectively. The first system was formed by two subsystems while the second was formed from three subsystems. In the latter case, two of the subsystem matrices were combined and the resultant matrix was combined with that of the third subsystem.

The Addition of a Line to a System

A variation of the matrix combining program would be the case where a system is changed by adding a line or a small network of lines. If more than one line is added, the network of these lines would be treated as a small system. The self and mutual drop coefficients for this small system could be calculated and then combined with the main system as outlined in the previous sections. However, the case of adding a single line resolves into a special case where the form of the equations is greatly simplified.

Consider this case of adding one line. To obtain this set of self and mutual drops, the original system is taken as subsystem A. A reference bus is now arbitrarily placed somewhere along this new line, and the two points where this line meets subsystem A are designated as tie points. The branch impedance of the new line may be proportioned in some manner to establish the impedance between the fictitious reference bus and the two tie points. This will establish subsystem B, consisting of the reference bus and two tie points. The self and mutual drop are now obtained for this system and consists of a two-by-two matrix. For this matrix D_{GG}^B and D_{GT}^B are zero so that the new equation corresponding to equation 44 is shown as equation 47.

$$\left\| \begin{array}{c} E_R^A - E_P^A \\ \hdashline E_R^A - E_G^B \\ \hdashline E_R^A - E_R^B \end{array} \right\| = \left\{ \left\| \begin{array}{c:c:c} D_{PP}^A & 0 & 0 \\ \hdashline 0 & 0 & 0 \\ \hdashline 0 & 0 & 1 \end{array} \right\| + \left\| \begin{array}{c:c} D_{PT}^A & 0 \\ \hdashline 0 & 0 \\ \hdashline -1_T^{A'} & 1 \end{array} \right\| \cdot \|C\| \right\} \cdot \left\| \begin{array}{c} I_P^A \\ \hdashline I_G^B \\ \hdashline I_R^B \end{array} \right\| \quad (47)$$

Since the row and column involving the reference bus of the subsystem B will not be needed in the final matrix for this case, the last row and column from this matrix can be deleted. Further, since the second row and column are zero everywhere, they can also be deleted. Thus, the calculation of the final self and mutual drop matrix for the case of adding a single line to a system for which the drop matrix is already known can be simplified. The matrix C as described previously is obtained and then its last row and column are deleted. Thus equation 47 can be reduced to

$$\|E_R^A - E_P^A\| = \|D_{PP}^A\| + \|D_{PT}^A\| \cdot \|C^*\| \cdot \|I_P^A\| \quad (48)$$

where the matrix C^* is the same as matrix C with its last row and column deleted.

Equation 48 now can be expanded to represent the entire self and mutual drop matrix.

$$\|D\| = \|D_{PP}^A\| + \|D_{PT}^A\| \cdot \|C^*\| \quad (49)$$

Conclusions

Although this method of obtaining the self and mutual drop matrix justifies itself economically, the elimination of tedious a-c network calculator measurements and the increased accuracy makes this method desirable from many standpoints.

When the self and mutual drop matrix is known for a system and the system is changed by adding a line or a group of lines, it is not necessary to reinvert the entire admittance matrix for the revised system. The drop matrix for this revised system can be obtained by combining the drop matrix for the original system with that of the additions lines using the method outlined here.

This method for combining self and mutual drop matrices also has the less obvious advantage of reducing the time needed to invert extremely large matrices. The time to invert a matrix increases quite rapidly as the number of busses is increased. Thus, by dividing a large system into two or three subsystems, inverting the matrices for these subsystems, and then combining these, the answer matrix can be obtained more economically than inverting the whole system matrix.

Discussion

E. E. George (Ebasco Services, Inc., Little Rock, Ark.): This derivation of a loss formula for an interconnected system is particularly welcome because it is adapted to direct use on an IBM *704* or a Remington-Rand *1103A*, or a similar large digital computer (smaller systems could be handled on a smaller type of computer).

The authors' method is not too difficult to follow, it is simple matrix algebra. Their method eliminates construction of a tree diagram or other manual analysis heretofore required.

The inversion of a nodal admittance matrix, after removing the reference bus row and column, is a powerful tool in circuit analysis. It changes admittance to impedance, converts a mesh to a star network with the old reference bus as the new neutral, the process is reversible, and as is well known, matrix inversion solves linear simultaneous equations in a convenient form.

Matrix algebra badly needs convenient symbols for the new matrix formed by adding or deleting a reference bus row and column to or from a previously designated matrix. While the authors follow the European use of a prime symbol as a superscript to denote transposition, some of us prefer the subscript t to denote transposition.

Also the asterisk symbol is generally used in mathematics and engineering to denote a conjugate.

R. W. Ferguson, R. W. Long, and L. J. Rindt: We would like to thank Mr. George for his interest. As he points out, the self and mutual drops are a powerful tool in circuit analysis work and with more and more of this type of work being programmed for high-speed digital computers, the use of these drops will undoubtedly increase considerably.

While the authors agree that some standard set of symbols are needed for matrix designations, the absence of standard symbols led them to use symbols that would not conflict with the various superscripts and subscripts of the submatrices, used in this particular development. It is hoped that with the growing use of matrix algebra, some standard set of symbols will be adopted.

Digital Computer Aids in Power-Pool-Operation Studies

Synopsis: This paper describes the use of a general-purpose digital computer as an aid in the solution of problems encountered in the pooled operation of a large hydroelectric system. This program has been used effectively during the past year by operations engineers of the Bonneville Power Administration (BPA). Its use has enabled studies of operations to be prepared more rapidly and in a form that can be used readily by management in analyzing current conditions and in formulating plans for subsequent operations.

THE 11 major utilities in the Pacific Northwest have been operating as a power pool since early 1940. The utilities operate in the states of Oregon, Washington, Idaho, Montana, and Utah, and in British Columbia, Canada. The resources in the area are predominantly hydroelectric and much is gained through co-ordination of the interconnected pool and nonpool generating facilities. The ability to take advantage of stream flow and load diversity has increased firm load-carrying capability by an estimated 1,000 mw (megawatts).

The installed capacity of the pool, including amounts available from interconnected nonpool utilities, is more than 9,000 mw of hydroelectric capacity and more than 1,000 mw of thermal generating facilities. Projects currently under construction or definitely scheduled will add 7,000 mw of hydroelectric capacity and 1,100 mw of thermal generating capacity. About 63%, or 10,100 mw, of the total hydroelectric facilities will be concentrated in a series of 17 projects. About 7,110 mw will be installed at the federal projects in this series. These projects are shown in Fig. 1, and start with Hungry Horse in western Montana on the upper reaches of south fork of the Flathead River, 1,150 miles from the Pacific Ocean at an elevation of 3,560 feet above mean sea level. The last of this series is the Bonneville plant only 150 miles from the Pacific Ocean, located at tidewater on the lower Columbia River. Several of the projects are not in operation but are either under construction or definitely scheduled. Projects under construction are John Day, Priest Rapids, and Rocky Reach. The Wanapum project is scheduled for construction after completion of Priest Rapids.

The importance of a co-ordinated operation on the series of 17 plants can be understood better when it is realized that they represent six different ownerships, private, public, and federal. The significance to this series of projects of pool operation is further emphasized when it

is realized that out of a total reservoir capacity of almost 20 million acre-feet, 67% is usable through all or part of this series of 17 plants. The large storage reservoirs and the magnitude of installed capacity make it possible for this series of projects to act as the leveling factor, or the balance wheel, for the entire pool. Grand Coulee is the key project, having some 5 million acre-feet of usable storage and 2,212 mw of generating capacity at full operating load.

A co-ordinating group is retained by power-pool members to develop seasonal analysis, collect and maintain current operating records, and to prepare in advance a pooled operating program for the subsequent year under critical and median month stream-flow conditions. It is necessary, however, for BPA to develop a pool-type analysis for plants shown in Fig. 1 in order to operate the federal system most effectively within the pool framework and yet to maintain the system's ability to meet all contractual commitments.

This requires a continuing analysis of pool operations by BPA as loads and resources diverge from original assumptions. The continuing expansion of the system has made it increasingly difficult to complete operation studies in time to keep management effectively informed on operating conditions. With the development of modern digital computers, it seemed only natural to investigate the possibility of developing a machine solution of the system operations problem. The program described in this paper has been written for the Bendix *G-15A* computer, although similar programs have been used on the International Business Machines Corporation *650* and the ALWAC IIIE computers.

The Problem

The problem is essentially one of setting up an efficient schedule of generation for the system of hydroelectric plants in order to meet an estimated load. Schedules are set up on a daily, weekly, monthly, and seasonal basis. The multi-decisions necessary in sequence, each one interdependent upon the previous de-

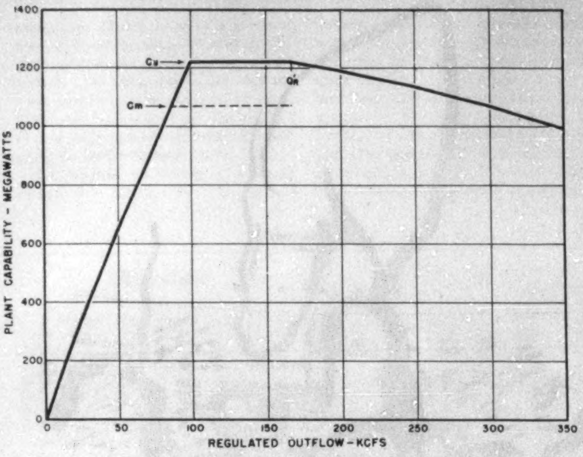

Fig. 2. Typical run-of-river plant characteristic curve

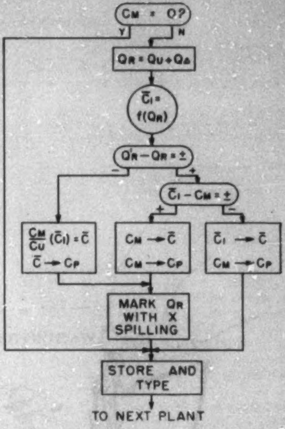

Fig. 3. Simplified flow chart for run-of-river plant

cisions, have precluded up to the present a rigorous mathematical treatment of the over-all problem of optimizing the operation of a large hydroelectric system. The computer program was developed around the practical method used by operating engineers of BPA in preparing studies employing the desk calculator.

In setting up the problem for desk calculator solution, the engineer operates the system in sequence, from the headwater plant, Hungry Horse, down through the Bonneville plant. If the first iteration does not produce the required total generation, a change is made in the operation of one or more of the reservoirs and the computation made again. In setting up changes, the engineer must be careful not to violate any physical constraints of the system.

Plant output and reservoir data are obtained from plant characteristic curves which have been put in tabular form to facilitate reading and to allow consistent interpolation between values when using a desk calculator. In the computer program these tables are stored in the memory and operated upon by means of table look-up and linear, single-interpolation subroutines. The tables have been reduced to as few points as is required to define the original curves within reasonable accuracy.

Nomenclature

The following symbols have been adopted in order to facilitate flow-charting and formulation of arithmetical expressions necessary for programming the problem.

$\bar{C}$ = energy capability
C_M = maximum capability during period
C_P = peak capability
C_U = ultimate capability limit
H/K = conversion factor
H/K_{FG} = full-gate conversion factor
F = forebay elevation
T = tailwater elevation
H = head
Q_D = flow resulting from storage draft
Q_M = modified inflow
Q_R = regulated outflow
Q_R' = flow at beginning of cutback
Q_U = outflow from upstream reservoir
Q_Δ = incremental inflow from upstream reservoir
Q_{max} = maximum or restricted flow
Q_{FG} = full-gate outflow
S = storage content
S_i = initial storage content
S_e = end storage content
S_Δ = change in storage content
t = length of period, days

Capability values are in megawatts; conversion factors are in megawatts per thousand second-feet; forebay, tailwater, and head values are in feet; Q values are in cubic feet per second; S values are in thousands of second-feet-days. A bar over a symbol indicates an average value.

Run-of-River Plant Representation

Run-of-river plants are represented by one curve of plant capability as a function of plant discharge as shown in Fig. 2. The curve stored in the computer is for the total or ultimate capability C_U of the plant. If, during the period under study, all units of a plant are not available, the capability limit C_M, which is entered as input data, is adhered to by appropriate logical decisions. If C_M is zero, the plant is not in service and the program skips to the next plant. The point at which rising flows cause plant capabilities to drop off because of reduced head is designated as the cutback point Q_R' in Fig. 2, and the capability will follow the curve or be proportioned down-

ward by the ratio of C_M to C_U if the flow exceeds this point. The plant data for each run-of-river plant are based on an average forebay elevation. No allowance in this program is made for operation of pondage at run-of-river plants due to the excessive memory space requirements.

A simplified flow chart for a run-of-river plant is shown in Fig. 3.

Storage Plant Representation

A storage plant is represented in the computer memory by several tables of characteristics which allow the computation of a head for any range of forebay and tailwater elevations, the determination of conversion factors, computation of peak and average output, tests for violation of restrictions or maximum flow, and other necessary functions. Several types of tables are common to all plants; however, each reservoir plant has some unique characteristic of its own which requires special handling. The tables required to define the four storage plants are shown in Table I. A simplified flow chart for the storage plant routine is shown in Fig. 4.

Operating flexibility of reservoirs is provided by means of codes entered as input data which allows the engineer to select the mode of operation as follows:

Code	Given Data
1	regulated outflow
2	flow resulting from storage draft
3	end of period storage content
4	restricted outflow (estimated)
5	full-gate discharge (estimated)

Codes 4 and 5 involve iterative loops which use the estimated given data for the first iteration. Each successive iteration uses the average of the first value and the computed value as the new given data and pulls out of the loop when a convergence test of 5 cubic feet per second is met. Generally three to five iterations are required for convergence depending on the value of the original estimate.

Code 6, as shown in Fig. 4, is provided to tune the complete system to a given load by varying the storage operation of any one of the four reservoirs at the option of the operating engineer. When using this code the operation of three of the reservoirs is fixed and the computer is instructed to meet the total system load by operation of the remaining reservoir. The load is actually given to the computer as the difference between the generation and the estimated total load. This difference is given as zero if the total load is to be met exactly. The logic in this operation is to provide a convenient way of computing steam replacement (if the difference is positive) or of dropping the nonfirm load (if the difference is negative). This operation includes within the overall iterative process, the iterative loops of codes 4 and 5. Convergence is quite rapid, however, because the conversion factors used in the solution are developed by the program operation. This process makes the operation quite stable in most cases and converges monotonically in two to three iterations. Oscillitory convergence results when spill is occurring at some plants below the reservoir which is being used to take the swing. In this case as many as ten iterations may be required.

In the event of an overdraft, an overfill, or the violation of a reservoir outlet restriction resulting from an invalid operating instruction, the computer types out an indicator of the violation along with a reservoir identification code, and then halts. The engineer must then specify an operation that will allow the computation to proceed.

Program Operation

Operation of the program for one period requires input data for each plant consisting of a stream flow and a maximum capability limit. In addition, the initial storage of each reservoir must be specified. In each subsequent period the initial storage content is carried over from the end content of the preceding period.

Because of the magnitude of the program, it was found necessary to store all the stream-flow and maximum capability-limit data on punched paper tape. These data are read into the computer via the photoreader for one period. The operating code and given data for each storage plant are entered via the typewriter for the first period and the computation started. Either a complete (long) or an abbreviated (short) typeout can be obtained as the computation proceeds. The usual method of operation consists of setting up the reservoir operation criteria for each period and running through the complete study, obtaining a short typeout for each period as it is computed. When this is completed, the results are reviewed and any necessary adjustments are made in the system operation by the operator in any period which seems to need modification. After the complete operation has been made, a long typeout covering all plants is made for each period.

Originally it was intended that very detailed data on each plant and reservoir would be included in the output format. This was given up, however, because of the memory capacity required just to store these data waiting for typeout. The typeout for run-of-river plants consists only of peak and average capability and plant discharge, while for a storage plant values for S_Δ, S_e, and H/K are typed out in addition. The short typeout previously mentioned includes only the storage plant data and a summary giving the total generation, load, and surplus. In many cases it has been found that the short typeout of a complete study is ample information; however, if the study is to be used by personnel not familiar with the program, a long typeout on a preprinted format with line and column headings is desirable.

Table II. Memory Requirements for 17-Plant Program

Item	Words
Run-of-river plant subroutine	47
Reservoir plant subroutine	229
Plant data tables	602
Table look-up subroutine	80
Setup for 13 run-of-river plants	196
Setup for four reservoir plants	73
Program logic	136
Loading in (includes decimal-to-binary)	155
Typeout (includes binary-to-decimal)	155
Lines 00 and 01 command lines	216
Line 19 input-output data	108
Line 15 input and computed data	108
Total	2,105
Available words (20 lines × 108) =	2,160

The normal operation of the program is to start with a given initial storage content of each reservoir and to determine an end content. It is frequently desirable to operate the storage in reverse in order to determine the initial storage content necessary to serve estimated firm loads or to develop the surplus available for secondary loads. Also, there are times when physical restrictions limit the outflow from reservoir plants and a reverse operation is required to determine the optimum rate of discharge. A supplementary program has been prepared which will make the necessary changes for the reverse operaton. This is accomplished by changing the algebraic sign of the storage draft operation and reversing the position of initial and end storage.

About 3 minutes are required to complete a computation and a long typeout for all 17 plants once stream flows have been loaded for one period and codes and given data typed in. This time may vary somewhat, depending on the number of iterative loops encountered in the operation.

Computer Requirements

Since the program was developed to allow an operating engineer to do his work more rapidly, it was considered essential that decimal-to-binary and binary-to-decimal subroutines be retained in the memory at all times to enable the engineer to "talk" to the computer without acquiring an intimate knowledge of what goes on inside the computer. This requirement, of course, uses memory capacity, but enables an engineer to learn the essentials of the program and to adapt himself to working with the computer quite rapidly.

Table II shows the allocation of memory space for the program, data, and subroutines. It can be seen that about 98% of the memory capacity is used.

Several subroutines were developed to optimize the program and to utilize the memory of the computer more effectively. In order that these subroutines may be used, certain data for the plant being computed must be placed in specific memory locations prior to entering the subroutine. Similarly, answers generated by the use of the subroutine must be stored in their appropriate positions in memory after the subroutine has completed its function. The grouping of these data have been termed a "setup" in the listings in Table II.

Certain redundancies purposely exist in the program logic as shown in Fig. 4. Since the computer has the unique feature of computing and simultaneously typing or punching the results developed in a previous iteration, the situation exists in many cases where the desired output is the limiting factor in completing a problem. Therefore, developing two or three functions twice in order to save program steps was determined a necessary economy.

Conclusions

Several conclusions can be stated based on experience gained from the development and use of the computer program described herein.

1. Studies can be prepared more rapidly, accurately, and neatly than can be obtained with desk calculators.
2. In addition to the more rapid solution of a problem, the results can achieve earlier and more widespread distribution by typing the output directly on vellum for easy, rapid reproduction of the results without intermediate clerical and typing operations.
3. Much more significant information can be made available to management for analysis in making operational policy.
4. In order to carry out the flow-charting and logic determinations for programming this problem, it has been necessary for the operating engineers to set down, in detail, experience factors which they have learned over a period of years. This forces a better over-all understanding of the problem by all personnel.

Continued research appears warranted in order to increase the effectiveness of the present program. The use of auxiliary storage devices is being investigated in order to enlarge the scope of the program. Research on an analytical approach to plant operation is being carried out in an effort to reduce the memory requirements for plant representation and to decrease the computation time.

Discussion

G. W. Bills (North American Aviation, Inc., Downey, Calif.): It is gratifying to read of the successful power-pool programming with the aid of the Bendix *G-15A* digital computer. When I was employed at BPA in 1955 there was considerable speculation as to the use of the Bendix *G-15A* on this problem because of the possible accuracy limitation of the computer and programming difficulties. What is your current appraisal of the use of the Bendix as compared with the ALWAC IIIE computer?

Obviously your next step will be to employ a large-memory-storage high-speed computer such as the International Business Machines Corporation *709* together with the necessary transducers and telemetering equipment for the purpose of almost instantaneously and continuously computing and controlling the Pacific Northwest power-pool operation. This will provide for the short-range program, but what is being planned for the long-range scheduling?

In 1954, if I remember correctly, the contract work being done at Massachusetts Institute of Technology for BPA on the optimization of water flow and minimization of electric line losses ended with the conclusion that at the moment there was no adequate solution because of the unpredictability of stream flows over long periods. Has any other attempt at solving this problem been made by BPA since then? It appears that with the increasing application of stochastic processes to industry, stochastic methods might be employed to produce long-range scheduling of water power in a more effective fashion, on the average, than assuming that because it is not possible to predict long-range flows, there is nothing that can be done.

H. M. McIntyre, C. W. Blake, and **J. S. Clubb:** Mr. Bill's discussion and continued interest in system operation problems are appreciated.

Programming difficulties of the *G-15A* have been overcome by thorough training in machine language programming. It has been necessary, however, for the machine language programmer to become more or less specialized, which would not necessarily be the case with a computer employing single-address-command system such as the ALWAC IIIE.

A program for use with an International Business Machines Corporation *704* is presently being written which embodies all of the features of the *G-15A* program plus control routines which eliminate operator intervention in the preparation of seasonal operating studies.

Since the termination of the research contract between BPA and Massachusetts Institute of Technology considerable effort has been spent by BPA on the development of long-range stream-flow forecasts. A semistatistical method of determining a "dependable" and a "probable" stream-flow estimate from 1 to 7 months in advance has been used quite successfully during the past 2 years. This method provides stream-flow forecasts which are used as input data for operation studies. This approach also provides a convenient method of determining flow forecasts of varying probability.

Logic for Applying Topological Methods to Electric Networks

R. T. BYERLY

C. W. KING
NONMEMBER AIEE

THE DETERMINATION of the behavior of large electric networks confronts the engineer or mathematician with the necessity of solving a large number of equilibrium equations determined by the network and the restraints imposed on it. This task has been sufficiently formidable to bring about the development and construction of large analog computers such as the d-c and a-c network calculators. In recent years, the availability of medium- and large-scale digital computers has provided a new facility for solving network problems. Considerable attention has been given to applying digital computers to load flow, transient stability, and short-circuit calculations.

For the most part, those engaged in this work have relied on nodal analysis methods because of the relative ease of establishing network relationships in the computer from basic topological and impedance data.

However, there are reasons to prefer in some cases to use the equilibrium equations obtained with mesh analysis. A reduction in the number of equations is often obtained. More stable coefficient matrices may speed convergence where iterative methods of solution are employed. The ease of handling mutual inductive coupling especially raises interest in the mesh analysis approach. The formation of mesh current equations by the analyst is of course a possibility, but this involves considerable time and effort for large systems.

These motives have led the authors to explore the possibility of forming mesh current relationships from raw system data using a large-scale digital computer. As will be seen shortly, the heart of the matter is concerned with the generation of a matrix which contains in usable form the information regarding network configuration which is needed to establish the required number of independent mesh equations. The logic required to obtain such a matrix is described for two different approaches. One method constructs the matrix a column at a time, the other constructs the matrix a row at a time.

Review of Some Geometrical Aspects of Networks

As an introduction to this problem, it would be well for the reader to review parts of the book by Professor Ernst A. Guillemin.[1] In the first chapter the motivation and the introduction to the application of topological methods to network analysis are quite clearly presented.

In developing a procedure for finding network relations by topological methods, we are solely interested in the network geometry, and therefore represent all elements as lines with small circles at the ends to designate the terminals. Such a representation is called a graph of the network. The graphs with which we will be concerned consist of these lines which

Y., June 22–27, 1958. Manuscript submitted March 14, 1958; made available for printing April 14, 1958.

R. T. Byerly, R. W. Long, and C. W. King are with Westinghouse Electric Corporation, East Pittsburgh, Pa.

The authors wish to express their appreciation to C. C. Li for his assistance in the early phases of this study. Mr. Li is a graduate student at Northwestern University and was employed in the Analytical Department of Westinghouse at East Pittsburgh during the summer of 1957.

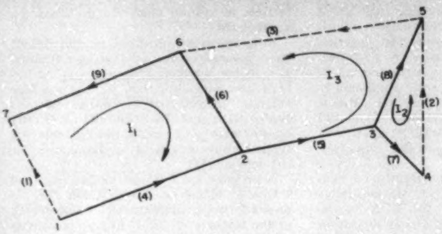

Fig. 1. Network no. 1 showing links, tree branches, and loops

we call branches and the small circles which we refer to as nodes. Using the nomenclature of Guillemin, we refer to the total number of branches of the network as b and the total number of nodes as n_t. This totality of branches for the network sets up a number of closed paths over which currents can circulate. It is apparent that by removing certain branches this property for carrying current will be destroyed. In Fig. 1 there is represented a network graph with $b=9$ and $n_t=7$. By removing the dotted lines, we destroy its current carrying property. These dotted lines are referrred to as links and the remainder of the network is referred to as the tree.

The tree has the particular property that it contains no closed paths. The lines which make up a tree will be called tree branches while the dotted lines are link branches. It is evident that for our given network graph several different trees could be found, however, the number of tree branches for each tree will always be equal to $n_t-1=6$. The number of link branches is therefore $b-6=3$. These formulas stem from the fact that a tree is said to consist of any set of branches in the given graph which is just sufficient to connect all the nodes. This is truly just n_t-1, for the addition of one more line would join two nodes which must necessarily have been connected and thus would create a closed path.

Professor Guillemin has shown that the values of the L link currents, where $L=b-(n_t-1)$, must fix all the currents of the network. That is, all the tree branch currents may be uniquely expressed in terms of the link currents. Therefore, there are only L independent currents in a netowrk and L is the smallest number of currents in terms of which all the other may be uniquely expressed.

We may thus uniquely express the state of the network in terms of L independent variables. Since each link causes a loop in the network to close, the current through that link can be used to identify one of the loop currents for the network. The correspondence between link and loop currents is shown in Fig. 1. Positive currents are assumed to flow from the low numbered node to the high numbered node in each branch. The branch currents are related to the loop or link currents in Fig. 1 by the following set of equations:

$I_1=I_1$

$I_2=I_2$

$I_3=I_3$

$I_4=-I_1$

$I_5=+I_3$

$I_6=-I_1-I_3$

$I_7=I_2$

$I_8=-I_2+I_3$

$I_9=-I_1$

In matrix notation:

$$\begin{Vmatrix} I_1\\ I_2\\ I_3\\ I_4\\ I_5\\ I_6\\ I_7\\ I_8\\ I_9 \end{Vmatrix} = \begin{Vmatrix} 1 & 0 & 0\\ 0 & 1 & 0\\ 0 & 0 & 1\\ -1 & 0 & 0\\ 0 & 0 & 1\\ -1 & 0 & -1\\ 0 & 1 & 0\\ 0 & -1 & 1\\ -1 & 0 & 0 \end{Vmatrix} \begin{Vmatrix} I_1\\ I_2\\ I_3 \end{Vmatrix}$$

Now designate the voltage drops (IZ) in the nine branches as:

$V_1,\ V_2,\ V_3,\ V_4,\ V_5,\ V_6,\ V_7,\ V_8,\ V_9$

and similarly the generation in the nine branches as

$E_1,\ E_2,\ E_3,\ F_4,\ E_5,\ E_6,\ E_7,\ E_8,\ E_9$

and note the Kirchhoff's law of voltages applied to each of the three loops gives the set of equations

$V_1-V_9-V_6-V_4=E_1-E_9-E_6-E_4$

$V_2-V_8+V_7=E_2-E_8+E_7$

$V_3-V_6+V_5+V_8=E_3-E_6+E_5+E_8$

In matrix notation:

$$\begin{Vmatrix} 1 & 0 & 0 & -1 & 0 & -1 & 0 & 0 & -1\\ 0 & 1 & 0 & 0 & 0 & 0 & 1 & -1 & 0\\ 0 & 0 & 1 & 0 & 1 & -1 & 0 & 1 & 0 \end{Vmatrix} \begin{Vmatrix} V_1\\ V_2\\ V_3\\ V_4\\ V_5\\ V_6\\ V_7\\ V_8\\ V_9 \end{Vmatrix} = \begin{Vmatrix} 1 & 0 & 0 & -1 & 0 & -1 & 0 & 0 & -1\\ 0 & 1 & 0 & 0 & 0 & 0 & 1 & -1 & 0\\ 0 & 0 & 1 & 0 & 1 & -1 & 0 & 1 & 0 \end{Vmatrix} \begin{Vmatrix} E_1\\ E_2\\ E_3\\ E_4\\ E_5\\ E_6\\ E_7\\ E_8\\ E_9 \end{Vmatrix}$$

If the coefficient matrix immediately above is designated T, then the coefficient matrix in the current relationship is T', the transpose of T. In general:

$TV_B=TE_B$

$I_B=T'I_L$

Now form an impedance matrix for the network for Fig. 1 as follows:

$$Z_B=\begin{Vmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} & Z_{15} & Z_{16} & Z_{17} & Z_{18} & Z_{19}\\ Z_{21} & Z_{22} & Z_{23} & Z_{24} & Z_{25} & Z_{26} & Z_{27} & Z_{28} & Z_{29}\\ Z_{31} & Z_{32} & Z_{33} & Z_{34} & Z_{35} & Z_{36} & Z_{37} & Z_{38} & Z_{39}\\ Z_{41} & Z_{42} & Z_{43} & Z_{44} & Z_{45} & Z_{46} & Z_{47} & Z_{48} & Z_{49}\\ Z_{51} & Z_{52} & Z_{53} & Z_{54} & Z_{55} & Z_{56} & Z_{57} & Z_{58} & Z_{59}\\ Z_{61} & Z_{62} & Z_{63} & Z_{64} & Z_{65} & Z_{66} & Z_{67} & Z_{68} & Z_{69}\\ Z_{71} & Z_{72} & Z_{73} & Z_{74} & Z_{75} & Z_{76} & Z_{77} & Z_{78} & Z_{79}\\ Z_{81} & Z_{82} & Z_{83} & Z_{84} & Z_{85} & Z_{86} & Z_{87} & Z_{88} & Z_{89}\\ Z_{91} & Z_{92} & Z_{93} & Z_{94} & Z_{95} & Z_{96} & Z_{97} & Z_{98} & Z_{99} \end{Vmatrix}$$

In this array, the diagonal terms are the branch impedances and the off diagonal terms are the inductive mutual impedances. One may write:

$V_B=Z_BI_B$

Multiplying on the left by T,

$TV_B=TZ_BI_B$

Substituting for I_B,

$TV_B=TZ_BT'I_L$

or finally,

$TE_B=(TZ_BT')I_L$

This last matrix equation is the set of mesh current equations required for the solution of a network. To establish this set of equations it is not only necessary to create a method for obtaining the T matrix but it is important that the method not be too cumbersome and unwieldy. The remainder of this paper describes two different approaches to this problem and the solution to which each approach has led.

A Method for Determining the Link Branches and the Tree Branches for a Given Network

The procedure to be followed in writing a transformation matrix T by columns consists of two parts: the first part is concerned with the separation of the network

Table I

branches into tables of link branches and tree branches and the second part concerns the formation of the matrix from these tables. The method of selection of links and tree branches is the same regardless of the complexity of the network and the same digital computer program will solve the problem for all cases.

As can be well appreciated, some orderly way of considering each branch of the network must be employed. This is accomplished through the use of a table which contains a listing of branches by numbers along with a designation of terminal node numbers for each branch. A separation of the branches into links and tree branches is based on data contained in such a table. The concepts which must be kept in mind in analyzing this data are best illustrated by considering a specific example.

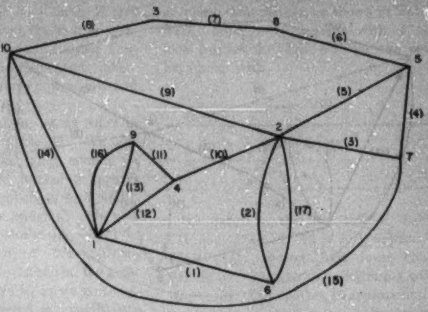

Fig. 2. Network graph for network 2

Consider the network shown in Fig. 2. Assume that each branch of the network has been given a line number from Table I which is a listing of all the branches of the network. Each branch is listed just once with the lower numbered node being listed first and the higher numbered node second. This in effect will set up the positive direction for every branch as we will consider the positive direction to be from the lower numbered node to the higher numbered node. Further it should be noted that in listing the branches of Table I, we first write down all the branches emanating from node 1, then all those from node 2, and then 3, etc.

Having formed Table I we prepare to form Tables II–V. Table II is the listing of link branches, Table III is to contain tree branches, Table IV is an auxiliary device which is used to establish the order in which successive nodes are examined, and Table V is a correspondence between original line numbers and the numbers assigned to links and tree branches in Tables II and III. Begin by saying that all branches through node 1 are tree branches and must be listed in Table III unless there are parallel branches. Since there are parallel branches between nodes 1 and 9, the second 1 9 branch closes a loop so it must be listed as a link branch in Table II. In Table IV we now place the numbers 4, 6, 9, and 10 which are the new nodes we meet in moving along the foregoing branches.

We now consider the first new node we have encountered, namely 4, which is listed first in Table IV. We go back to Table I, ignoring node 1 since branches through node 1 have already been accounted for, and hunt for all branches through 4. The first one we find is the branch 2 4. Since node 2 has not been used before, branch 10, which connects nodes 2 and 4 cannot possibly close a loop. It is therefore entered in Table III as a tree branch the node 2 is placed in Table IV just to the right of node 10. The next branch is 4 9. Remember that node 9 appears to the right of 4 in Table IV and therefore we have previously used node 9; 4 9 must close a loop so it is a link and should be entered in Table II. There are no more 4's in Table I, so we never have to consider 4 again. This is shown in Table IV by putting a check above the 4.

The next node in Table IV is 6, so we will return to Table I to find all branches through node 6. Again we ignore the 1's. The first branch containing a 6 is 2 6 but the number 2 appears to the right of 6 in Table IV; therefore, both nodes 2 and 6 have been used before so 2 6 is entered as a link in Table II. The next 6 is encountered as 2 6 which is a parallel branch to the first 2 6 branch therefore, it too must be entered into Table II as a link. There are no more 6's so that a check is put in the first line of Table IV above the 6.

The next number appearing in Table IV is 9 so we must find all 9's in Table I. The first 9 appears in 4 9. Now since 4 appears to the left of 9 in Table IV, branch 4 9 has been considered before so should now be passed over. We have now exhausted the 9's, so we check off 9 in Table IV and pick up the next number appearing there.

We must now find all 10's appearing in Table I. We first encounter 2 10; 2 appears to the right of 10 in Table IV,

Fig. 3. Link and tree branch graph for network 2

therefore 2 10 must be entered in Table II as a link. The next 10 in Table I appears as 3 10, since node 3 does not appear in Table IV, it is written in Table IV and the branch 3 10 is entered into Table III as a tree branch. The next 10 appears in Table I as 7 10; the 7 does not appear in Table IV so it is written in Table IV and the branch 7 10 entered into Table III as a tree branch. This exhausts the 10's so a check is placed above the 10 in Table IV.

In the foregoing manner we now consider all the 2's in Table I, then all the 3's all the 7's, the 5's, and the 8's. Table II now contains all the link branches and Table III all the tree branches.

We now fill in the first column of these tables starting with Table II and the number 1 and reassign new line numbers to these links and tree branches. The new line numbers facilitate the formation of the transformation matrix T by columns. Table V is now formed as a coordinating table which sets up a correspondence between the new branch numbers and those appearing in Table I.

The general flow of logic used in the procedure for obtaining the link and tree branches is shown with the block diagram in Fig. 4. The given network is redrawn in Fig. 3. In this figure, the tree branches are shown as solid lines and the link branches as dotted, the arbitrary directions are shown and each line is numbered according to the new assignment shown in Table V.

FORMATION OF THE TRANSFORMATION MATRIX T BY COLUMNS

Consider again the T matrix previously written for the network of Fig. 1. Write branch numbers above the columns and link numbers before the rows as shown below:

$$\begin{array}{c|ccccccccc}
 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\
1 & 1 & 0 & 0 & -1 & 0 & -1 & 0 & 0 & -1 \\
2 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & -1 & 0 \\
3 & 0 & 0 & 1 & 0 & 1 & -1 & 0 & 1 & 0
\end{array}$$

Note that the columns of the T matrix may be regarded as relationships which determine each branch current in terms of link currents. The branches 1, 2, and 3 are links, hence the branch currents I_1, I_2, and I_3 are identical to link currents. The first three columns and rows constitute a 3 by 3 identity submatrix. In general, given n links, the T matrix formed using the procedure to be described will have as a submatrix an n by n identity matrix. The problem is thus reduced to forming the remaining columns of the matrix. The fundamental ideas needed for the formation of these remaining columns are:

1. Kirchhoff's Law which states that the sum of all currents at a node must equal zero.
2. Every branch current may be expressed in terms of one or more link currents.

Now let us again turn our attention to the network of Fig. 3, and examine node 4 of the network. If B_9 represents the current in branch 9, and $L2$ the current in link 2, we may state that

$$-B9-B13+L2=0$$

where the minus sign indicates current into the node and the plus sign indicates current out of the node. Further,

$$B9=-B13+L2 \qquad (1)$$

Before we can express $B9$ in terms of link currents, we must certainly express $B13$ in link currents and then substitute this value in equation 1. Upon examination of Fig. 3, we see that if we go to node 2 we may write

REPEAT PROCEDURE FOR NEXT NODE NO. IN TABLE 4
①

Fig. 4. Flow diagram for selecting links and tree branches

$$B13+L3+L4+L6+L5+B16=0 \qquad (2)$$

while node 5 enables us to write

$$-B16+L8+L7=0 \qquad (3)$$

Substitution from equations 2 and 3 into equation 1 gives

$$B9=L2+L3+L4+L5+L6+L7+L8$$

It is apparent that in order to express $B9$ in terms of links, it was necessary to include the definition of branches 13 and 16 in terms of links. We may think of branches 9, 13, and 16 as making up a chain of branches or a limb of our original tree. It is this notion that we wish to use and through its use develop a relatively easy method for expressing each branch current in terms of link currents. To accomplish this, we will next develop Tables VI and VII which list all nodes except node 1, and all links through each node in Table VI and all branches through each node in Table VII. Node 1 is omitted from Tables VI and VII because it is possible to establish only 9 independent branch current relationships for the network of Fig. 3.

Table VI

Node	Link
2	3, 4, 5, 6

5	−16
6	−10
7	15
8	−17
9	−11
10	−12, −14, −15

The general rule is the same for obtaining Table VI and Table VII. However, Table VI is obtained from using Table II while Table VII is obtained from Table III. The rule states that to fill in Tables VI for a given node, we first examine the right hand column of Table II and pick out all those places where this node occurs noting the link number for each of these places. Each of these link numbers is listed along side the node number in Table VI, with a plus sign being given the link number if the node number occurs under R in Table II and a minus sign being given the link number if the node number appears under C in Table II. This sign convention differentiates between currents flowing into and out of the node.

In way of illustration, let us list 2 in our node column of Table VI. We now proceed to the right hand column of Table II. Our node number 2 appears under R for link numbers 3, 4, 5, and 6 but does not appear under C. We now list these numbers along side our 2 in Table VI with plus signs. We next consider node 3, 4, etc., filling in the right hand column of Table VI as we go along. Table VII is completed in exactly this same manner, though we appreciate the fact that we must use Table III in order to pick out the necessary branches.

A few remarks on the makeup of Table VII would be in order. First we observe that each branch can appear no more than twice in the table and that if a branch appears twice it will appear with different signs as we are looking at it from each of the two nodes at which it terminates. Since there are only n_t-1 tree branches, we can say that there will be less than $2(n_t-1)$ numbers appearing in the second column of Table VII as node (1) does not appear in the table. Further, we see that every node listed in the left hand column of Table VII cannot be followed by two branch numbers in the right hand column. For if this were possible, we could get completely from one node back to itself again by means of tree branches and this would close a loop. We would therefore have an error in our Tables VI and VII. We can thus certainly say that there is at least one node listed in Table VII which has only one tree branch joined to it. The significance of this fact will become apparent as the process develops.

Before we proceed to the picking out our tree limbs, we can remark that since there are 8 links and 9 tree branches our T matrix will consist of 8 rows and 17 columns. Since branch 1 really means link 1 and branch 2 is link 2, etc., we see that the first 8 columns with the first 8 rows form an 8 by 8 identity matrix. So we are really concerned only with columns 9 through 17 of our T matrix at this time.

DESIGNATION OF LIMBS

Since column 9 of our matrix is the first one to be found, we look for the row of the right-hand column of Table VII which begins with 9 or −9. We see that 9 appears as −9 and has a −13 appearing with it. These two numbers are placed in a limb defining box as shown in Table VIII. Since −13 appears with 9 we look further in Table VII for the row beginning with 13.

Table VIII

Limb Branches		
−9	−13	16

It appears in the first row of Table VII along with 16; 16 is now written in Table VIII, and we look down Table VII till we find the row beginning with 16 or −16. The number 16 appears in the fourth row by itself so we have defined our limb which begins with branch 9. We now go to Table III and define our limb in terms of the nodes through which it passes. This is shown in Table IX.

Table IX

Limb Nodes					
1	4	2	4	2	5

Branch 9 passes through nodes 1 and 4, branch 13 through nodes 2 and 4, branch 16 through nodes 2 and 5, these are listed in Table IX. It is inherent to the process that the first node in the limb consisting of branches 9, 13, and 16 is not used in defining branch 9 in terms of links. The reader may verify this by reconsidering equations 1, 2, and 3. Hence, delete the first node number in Table IX. In this case it is a 1. We further delete the second 4 and second 2 which appear in Table IX, all repetitions of numbers are always deleted. This leaves 4, 2, and 5 as the nodes through which this limb passes. We now refer to Table VI under the node column and we write down the links which pass through these nodes. We obtain: link 2 passes through node 4, links 3, 4, 5, 6 pass through node 2, and links 7 and 8 pass through node 5. This defines branch 9 in terms of links and the ninth column of the T matrix appears in Table X. If one of the links had a minus sign, a −1 would have been put into the proper space of column 9.

Fig. 6. Flow diagrams for selecting limbs and the formation of T matrix by columns

As another example, let us obtain column 10 of our *T* matrix, that is we will define branch 10 in terms of links. From Table VII we see that −10 appears by itself so our limb is defined as just −10. This corresponds to Table VIII for our previous case. From Table III we obtain nodes 1 6, this corresponds to Table IX for the foregoing case. The number 1 is deleted and we have just the 6 to look up in Table VI. Through node 6 we have −link 3 and −link 4; this gives column 10 as listed in Table X.

Let us suppose that we wish to obtain column 14 of the *T* matrix. The second line of the right hand column of Table VII begins with 14 so that our limb branches are 14 and 17 since 17 appears by itself in line 7 of Table VII. Using Table III, our limb nodes are 3, 10, 3, 8. Again, since node 10 is the first node in the limb composed of branches 14 and 17, it is not used in defining the current in branch 14. As before, this can be verified by writing the appropriate current equations from Fig. 3. Thus, the second number, 10 in this case, is deleted from our limb nodes. Further we delete the second 3 from our limb nodes which leaves us with nodes 3 and 8. We now proceed to Table VI and see that there are no links through node 3 and only one through node 8. It is −8. $A+1$ is now placed in row 8 of column 14. It should be pointed out that writing column 14 is equivalent to solving the following equation for $B14$:

$$B14+L8=0$$

and the reason for the sign change is thus apparent.

The rule is this: Having obtained the limb nodes, we have two cases:

1. If the first branch number of the limb branch set is negative, the first node is deleted from the limb node set as well as all repetitions appearing in the limb node set. Plus 1's and minus 1's are added to the proper row of our branch column of the *T* matrix just as the links appear as plus or minus in Table VI.
2. If the first branch number of the limb branch set is positive, we delete the second node from the limb node set as well as our repetitions. This time, we pick out all links from Table VI and change their signs before adding them to the proper row of the *T* matrix.

It is possible that having chosen the set of limb nodes, we may proceed to Table VI and find that two different nodes pick out the same link. In this case the link will appear with opposite signs and the +1 and −1 when added to the proper place in our column will have the effect of putting in a zero at this location. Our *T* matrix can never contain a number different than 0, 1, or −1.

The complete *T* matrix for our sample network is shown in Table XI, while the block diagrams showing the logic for obtaining Table VI and VII appear as Fig. 5, and that for obtaining the limb nodes from Tables VI and VII is shown in Fig. 6.

FORMATION OF A TRANSFORMATION MATRIX T BY ROWS

The attempt to find a logic for formation of a transformation matrix by rows in many ways seems more natural than

Table XII

attempting the method described in the preceding section. The authors have studied this approach and present the results of this study in the following paragraphs. There do appear to be certain inherent differences in the matrices obtained by the two methods. A discussion of these differences is perhaps best reserved until after a description of the method is presented.

This logic will be domonstrated for the network graph of Fig. 2. The data required to form the matrix are contained in Table I. The branches of the network are not separated into links and tree branches in the procedure to be described here. The following ideas will guide the formation of the matrix by rows:

1. The number of rows (independent loop equations) required is $[b-(n_t-1),]$ in this case $[17-(10-1)]=8$.

2. Each branch in the network must appear somewhere in one of the loop equations, meaning that there must be at least one nonzero term in each column of the T matrix.

3. The matrix will be formed using the least number of nonzero elements in each row. That is, all the loop equations involving just two branches will be formed, then all those involving three branches, and so forth. The process of finding new rows will be stopped when enough rows of the matrix have been formed to meet the requirement stated in item 1 of the foregoing. The procedure will be such that the requirement stated in item 2 of the foregoing will automatically be satisfied when the proper number of rows has been written.

To begin, the information of Table I is used to form Table XII. The blocks of data in Table XII simply show for each node of the system the manner in which that node is connected to other nodes. For instance node 1 is connected to node 4 by branch 12, to node 6 by branch 1, to node 9 by branches 13 and 16, to node 10 by branch 14. It has been stated earlier that the reference positive direction for current, voltage drop, or voltage source will be assumed to be from the low numbered node to the high numbered node for every branch. This accounts for the negative signs which are associated with some branches in Table XII. Note for instance that node 7 is connected to node 2 by branch (−3), to node 5 by branch (−4), and to node 10 by branch 15. The necessity for employing these negative signs in this manner will soon be apparent. Every branch appears twice in Table XII, and while it is not absolutely essential to rely on having the data in the form of this table, some clarity is believed to result.

With Table XII available, attention is turned to writing all the rows which contain just two nonzero elements. These loops containing two branches occurs only if parallel branches exist. To select the rows with two nonzero elements, proceed as follows. Begin at the top of Table XII and note that node 1 is connected to node 4 by means of branch 12. Then transfer to the node 4 connections to determine whether or not node 4 is connected to node 1 by any branch other than (−12). Obviously, the branches (12, −12) do not close a loop, and a programmer will need to provide a simple check to avoid this absurdity. Node 4 is not otherwise connected to node 1, so return to the node 1 connections and progress downward one line in Table XII and find node 1 connected to node 6 by branch 1. Transfer to the node 6 connections and determine that node 6 is not otherwise connected to node 1. Return to the node 1 connections and find that node 1 is connected to node 9 by branch 13. Transfer to the node 9 connections and determine that 9 is connected to 1 by branch (−16). The first loop containing two branches then consists of lines (13, −16).

At this point, we mark the first element used in forming this loop by a double asterisk and all other elements used in forming the loop by a single asterisk. The purpose in so marking these branches is to be able to make the selection of loops

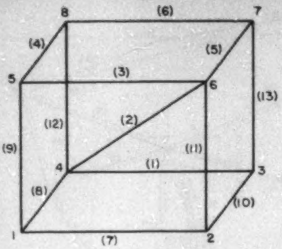

Fig. 8. Graph of nonmappable network 3

as the process continues without the necessity for checking to be sure that the loops chosen are independent. The purpose of the two different markings will be explained shortly. For the present, we will simply state that new rows will be begun using unmarked elements. Marked elements may be used elsewhere in forming a loop, but not as the first element. The second use of an already marked element does not alter the mark previously given that element.

Return to the node 1 connections and sensing the mark associated with branch 16, skip to the next line and proceed as outlined. By this procedure, the one remaining row with two nonzero elements will be found to correspond to the loop formed by the branches (2, −17).

When the table has been completely searched for two element rows, the search for rows containing three nonzero elements begins. Again starting at the top of the table, trace from 1 to 4 by the way of branch 12, then from 4 to 2 by the way of branch (−10), and then search the node 2 connections for a return to node 1. None exist, and so a new attempt to find a closed path must be made. One could return to the list of node 1 connections and advance one line, but this overlooks the possibility of finding a closed path by leaving node 4 using a different branch. Hence, return to the node 4 connections and note that 4 is connected to 9 by branch 11. The node 9 data will show a return to node 1 by branch (−13). Hence, a loop consisting of the branches (12, 11, −13) has been discovered. The new branches used for the first time should be marked immediately. Return now to the node 4 connections and determine that there are no more branches out of node 4 to be considered at this time.

Then return to the node 1 data and advance one line. By repeating the procedure just outlined, one determines that a row containing three nonzero elements cannot be obtained starting with branch 1. No attempt to start new rows with branches 13 or 16 will be made since thay are marked. The remaining three element rows are (5, 4, −3) and (9, −15, −3).

Of course the number of rows written is tabulated, and at the end of the writing the rows with three nonzero elements, there are still three rows to be written, so a search is begun for the rows containing just four nonzero elements. Following the procedure outlined in the foregoing. one discovers the loops corresponding to (1, −2, 10, −12) and (14, −9, 10, −12). The remaining row contains 5 nonzero terms and corresponds to the loop (7, −6, −5, 9, −8). The T matrix for this network using this procedure is shown in Table XIII.

The reason for the double asterisk is not brought out in this example. This is due to the fact that we were able to begin the eighth row with an element that had not previously been used. The decision as to where to begin the eighth row in order to obtain an independent loop was straight forward. However, suppose that the seventh row had included the last remaining unused element. Then some decision as to the point of beginning the eighth row would be required. By eliminating all the lines in Table XII which have been marked with a double asterisk, we would be able to begin the process all over with no concern that the rows yet to be written might not be independent.

There are some differences between this T matrix and the one written by columns. Note that there is no renumbering of branches. The loop currents, shown in Fig. 7, are not each identical to one of the branch currents. There is no 8 by 8 identity part of this matrix. It does, however, have the important properties associated with the matrix written by columns, namely

$$TV_B - TE_B = 0$$

and

$$T'I_L = I_B$$

where V_B and E_B are branch voltage drop and branch voltage source column vectors, and I_D and I_B are loop current and branch current column vectors.

APPLICATION TO A NETWORK NOT MAPABLE ON A SPHERE OR PLANE

The logic described in the two preceding sections is not restricted in its application to networks mapable on a plane or sphere. The cube with a diagonal shown in Fig. 8 may be used to demonstrate that no difficulty is encountered in forming a transformation matrix by either method. The matrix resulting from formation by columns is presented in Table XIV and the one by rows is presented in Table XV.

Conclusions

Methods have been described for forming a transformation matrix T by columns and by rows. Such a matrix contains the information regarding network configuration which is needed to establish the required number of independent mesh equations. The methods as presented are suitable for programming a digital computer. Experience in using T matrices formed by the two methods may very well establish a preference for one method over the other for certain types of problems. Considering several imme-

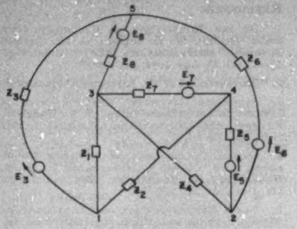

Fig. 9. Network 4

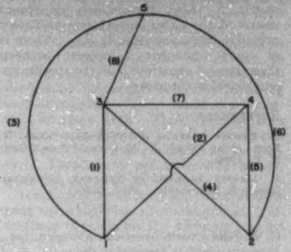

Fig. 10. Graph for network 4

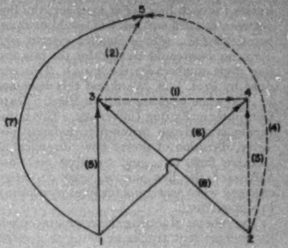

Fig. 11. Link and tree branch graph for network 4

diate applications, the authors chose to work with the formation of the matrix by columns, and a program for obtaining the matrix has been written for and used with the IBM *704* located in the Analytical Department of Westinghouse in East Pittsburgh. The following times were noted:

No. of Nodes	No. of Branches	Machine Time in Seconds
37	57	27
65	92	35
95	151	50

The times recorded here include reading data from cards and writing the final matrix on tape. The large portion of the time was used in reading cards and writing the answer tape.

Appendix

The purpose of this appendix is to show a complete solution of a network problem using a transformation matrix T to establish the network relations. The network solved here is shown in Fig. 9.

Suppose the network constants and the impressed voltages in per unit are as in Table XVI. The graph of the network will be as shown in Fig. 10, and Table I for this network will be as follows:

Line Nos.	Branch Node Designations	
1	1	3
2	1	4
3	1	5
4	2	3
5	2	4
6	2	5
7	3	4
8	3	5

The network will have the tree branches and links shown in Fig. 11. The new branch numbers are included with the table of constants. Using the method of columns we obtain the following T matrix.

Link Number	Branch Number 1	2	3	4	5	6	7	8
1	1	0	0	0	1	−1	0	0
2	0	1	0	0	1	0	−1	0
3	0	0	1	0	1	−1	0	−1
4	0	0	0	1	1	0	−1	−1

The Z matrix for this network will be as follows:

$$\begin{Vmatrix}
1+j0.2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0.2+j0.3 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0.2-j0.5 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0.8+j1.0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0.1+j0.3 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0.05+j0.15 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0.2+j0.6 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1+j0.5
\end{Vmatrix}$$

Following the procedure outlined in the text, the equilibrium equations are:

$$TE_B = TZ_B T' I_L$$

$$\begin{Vmatrix}
-1.75+j0 \\
-1.7-j0.18 \\
-0.7-j0.1 \\
-1.1+j2.62
\end{Vmatrix}
=
\begin{Vmatrix}
1.15+j0.65 & 0.1+j0.3 & 0.15+j0.45 & 0.1+j0.3 \\
0.1+j0.3 & 0.5+j1.2 & 0.1+j0.3 & 0.3+j0.9 \\
0.15+j0.45 & 0.1+j0.3 & 0.45+j0.45 & 0.2+j0.8 \\
0.1+j0.3 & 0.3+j0.9 & 0.2+j0.8 & 1.2+j2.4
\end{Vmatrix}
\begin{Vmatrix}
I_1 \\
I_2 \\
I_3 \\
I_4
\end{Vmatrix}$$

These equations have the following solutions:

$I_1 = -1.23633+j0.666294$
$I_2 = -1.167166+j0.537270$
$I_3 = 0.151991-j1.184075$
$I_4 = 1.156179+j0.961608$

The remaining branch currents may be determined using rows 5, 6, 7, and 8 of T' and the link current vector. The values obtained are:

$I_5 = -1.09533+j0.98109$
$I_6 = +1.08434+j0.51778$
$I_7 = 0.01098+j1.49888$
$I_8 = -1.30817+j0.22246$

Table XVI

Original Branch Numbers	Branch Impedances, Pu	Impressed Voltage, Pu	New Branch No.
1	0.1+j0.3		5
2	0.05+j0.15		6
3	0.2+j0.6	1.0+j0.08	7
4	0.1+j0.5		8
5	0.2−j0.5	−0.7−j0.1	3
6	0.8+j1.0	−0.1+j2.70	4
7	0.1+j0.2	−1.75+j0	1
8	0.2+j0.3	−0.7−j0.1	2

◆

Discussion

E. E. George (Ebasco Services Inc., Little Rock, Ark.): The systems of line and bus numbering used by the authors provides completely independing numbering for both groups. There is an improvement in the numbering system that could be made to simplify the explanation as well as the computer coding. In this new procedure busses could be assigned three digit numbers and then the lines could be denoted by a number with twice as many digits, comprised of the numbers of the two terminal busses for each line. For instance, the line between bus 036 and bus 243 would be numbered 036243. (On a smaller system two digit numbers could be used for the bus and four digit numbers for the lines.) This was done by Prof. J. B. Ward and this discusser in 1956 when working with an Electro-Data Computer at Purdue University. This numbering system can be used to indicate polarity, direction of power flow, direction of reactive flow, etc., and the first and last halves of the line number can be interchanged when searching for lines connecting to a given bus.

The scheme of letting the computer select the independent tracks or loops in a mesh system is a valuable development and the authors are to be highly praised. This task has always been the most tedious operation in working with a mesh network, and it has been a major source of errors.

The selection of independent, necessary, and sufficient equations in a large mesh network is so difficult by manual methods that the mesh method has come near being discarded as a practical tool. Now that the computer can be used to do this difficult chore, we may find more uses for mesh network methods.

This discusser developed a process chart in 1937 for tracing mesh tracks on a computer, but it was never coded or applied to a particular type of computer. He, therefore, has an appreciation of the practicability and utility of such an application of Messrs. Byerly, Long, and King have described.

The authors use the word "link" to denote a branch that is not a tree branch. This discussor prefers the term "air branch" instead of "link." A mesh would then be composed of "tree branches" and "air branches," with each term being descriptive and therefore easier to remember.

L. K. Kirchmayer and **A. J. Wood** (General Electric Company, Schenectady, N.Y.): The authors' presentation of a logical technique for the computer generation of a connection matrix is interesting and will undoubtedly be of value to engineers and others concerned with the digital computer solution of electric networks.

The equations under the section on "Review of Some Geometrical Aspects of Networks" of the paper are in essence a specific application of G. Kron's general laws of transformation.[1,2] These laws of transformation may be stated as:

if

$$\bar{I}^{\text{old}} = \bar{C}\bar{I}^{\text{new}}$$

then

$$\bar{E}_{\text{new}} = \bar{C}_t{}^*\bar{E}_{\text{old}}$$

$$\bar{Z}_{\text{new}} = \bar{C}_t{}^*\bar{Z}_{\text{old}}\bar{C}$$

where the subscripts old and new refer to the old and new circuits respectively and I, E, and Z denote the corresponding current, voltage, and impedance matrices. The matrix $\bar{C}$ is often referred to as Kron's connection matrix. The matrix $\bar{C}_t{}^*$ is the conjugated transpose of $\bar{C}$.

If the branch currents and voltages are designated by the matrices $\bar{I}^{\text{old}}$ and $\bar{E}_{\text{old}}$ and the loop or link quantities by $\bar{I}^{\text{new}}$ and $\bar{E}_{\text{new}}$, then the authors' specific transformation matrix T' corresponds to Kron's connection matrix $\bar{C}$. Also, the branch impedance matrix of the paper corresponds to Kron's primitive impedance matrix $\bar{Z}_{\text{old}}$. There is of course complete agreement between these general equations and the specific example used in the paper.

G. W. Bills (North American Aviation, Inc., Downey, Calif.): Inevitably the marriage of topological methods and digital computers for the automatic solution of electric networks had to occur. In 1938 the discusser was a graduate student under Professor Cramlet at the University of Washington when the latter began his research into the geometrical properties of electric networks and which resulted in the classic paper by Prof. Cramlet and Ingram.[1] Just previous to this time Gabriel Kron began publishing his papers on tensor analysis of networks.[2] Unfortunately there were no high-speed, large-memory electronic digital computers available then to make it practical to apply such methods to large electric networks. The papers by Wong[3] and Glimn[4] were among the first to do this. The present paper is of interest because it supplies a needed tool when large electric networks must be analyzed by the mesh approach; and it demonstrates the effectiveness of the topological technique when combined with a computer such as the IBM *704*.

This paper rightfully recognizes that iterative methods are just as applicable to the solution of mesh current equations as to nodal equations. Strangely, most papers which apply mesh analysis to power system analysis have resorted to matrix inversion, a process usually inferior to iterative techniques for large systems.

I should like to point out that mutual inductances can readily be included in nodal equations, as demonstrated in a paper[5] presented at the AIEE Pacific General Meeting in August 1958. For this reason it is not necessary to resort to mesh analysis when mutual inductances are present in a system.

A little over a year ago our Analysis Unit began studying Guilleman's excellent study[6] for the purpose of applying topology to the automatic coding of networks with an IBM *704*. Unfortunately the cancellation of the NAVAHO missile program brought a sudden and prolonged halt to our digital programing activities. For this reason we are especially grateful to know that a digital program such as the one described in the paper is in existence. Is this program now listed with SHARE or at least available to IBM *704* users?

Any systems engineer or circuit theory analyst should appreciate the simplicity of this program for obtaining a T matrix. Because the method is so clear, it appears that clerical help could be quickly taught to number nodes and branches, form Table I, and then place the values on data sheets for entry into the digital computer, thus releasing engineer for more creative tasks.

Have any networks been found where the program could not form a correct matrix?

6. INTRODUCTORY CIRCUIT THEORY (book), E. A. Guillemin. John Wiley & Sons, Inc., New York, N. Y., 1953.

Ernest J. Schubert (Burroughs Corporation, Paoli, Pa.): This paper describes a computer analysis for networks of higher complexity. Branches are somewhat confusingly denoted in four different ways by line no. (Table I), by both the nodes, link and tree numbers equivalent to a "new branch no." (Table V). No consistency can be seen in numbering nodes or branches.

Better efficiency in dealing with similar problems may be gained by organizing the concept differently:

1. Only one branch shall be considered connecting any two nodes. Parallel paths between the same nodes have to be combined in a single equivalent branch.

2. The number of nodes N determines the possible complexity of a net, because the number of branches B cannot exceed the combinations of n things taken two at a time.

$$B \leq N(N-1)/2$$

3. In opposition to the section on "Application to a Network not mapable on a Sphere or Plane" it should be noted that any net may be mapped in a plane. Intersecting branches might occur for more than three nodes without being relevant for the solution. If drawing a netgraph at all, nodes shall be arranged approximately in a circle, numbering the nodes in sequence.

4. Nets comprising N nodes might be formed depending on the number of branches B between two extremes:

complete web $W=(N-1)N/2$
tree $T=N-1$

Branches in excess of those forming the tree are links L. Their number has an upper bound.

$$L = B - T \leq W - T$$

5. A net comprising N nodes is completely described by a matrix with N rows i and columns j describingo rigin and destination of any possible branch by a branch impedance $Z_{ij} = Z_{ji}$ considering $i<j$ only. Because of symmetry and insignificance of Z_{ii} (node connected to itself) $N(N$-$1)/2$ storage locations in the computer are required only.

6. To determine without tabulation links and loops by computer routine an image matrix S is formed with:

$S_{ij}=0$ for $Z_{ij}=0$
$S_{ij}=1$ for $Z_{ij}\neq 0$

Forming S^2, S^3 gives the required information for computer instruction as follows:

6.1...$S_{ii}^2=C$...the node i is connected to C other nodes
6.2...$S_{ii}^3=0$...the node i is single ended and does not belong to any loop
6.3...$S_{ii}^3=2$...the node i is part of one loop
6.4...$S_{ii}^3=4$...the node i is part of two loops, etc.

From S_{ii}^3 and S_i a subroutine may directly eliminate links to form a tree.

It is regrettable that the pioneering efforts of G. Kron in his classic book[1] have not been mentioned as the most pertinent reference.

REFERENCE

1. See reference 1 of Mr. Kirchmayer's discussion.

Martin J. Lantz (Bonneville Power Administration, Portland, Oreg.): The authors are to be commended for this fine paper. This method is applicable to short-circuit solution of power system networks and does include mutual coupling between circuits for zero-sequence circuit problems. The discusser has had experience in this type of problem for the IBM *650* digital solution.[1] Since the reference 1 paper was published the average fault solution time has been reduced by a factor of three and considerable simplification made in the problem preparation.

It is my feeling that the mesh approach to this problem is the more practical for the average utility engineer.

In prior discussion with the author, the then assumed method of establishing faults was to include an element for every fault position which practically doubles the size of the impedance matrix. This large matrix must be inverted once and the large inversion multiplied by the T matrices for each fault. It seems that the subsequent matrix multiplications with the very large matrix inversion may result in greater solution times than the method described in reference 1 which requires an inversion of a matrix of half the size for less than one third of the faults in the revised program.

It is not clear how the authors intend to represent other than bus faults, such as faults on either side of a line breaker after the breaker has opened for circuits involving mutual coupling. These faults are important for relay work. Three terminal lines require a sequential opening of circuit breakers which further complicates the solution. These faults are all readily accomplished in the reference solution.

It is hoped the authors will continue their program to cover an automatic solution of all positions of faults for the mutually coupled networks.

1. DIGITAL SHORT-CIRCUIT SOLUTION OF POWER SYSTEM NETWORKS INCLUDING MUTUAL IMPEDANCE, Martin J. Lantz. *AIEE Transactions*, vol. 76, pt. III, 1957 (Feb. 1958 section), pp. 1230–35.

R. T. Byerly, R. W. Long, and C. W. King: The authors appreciate the many fine comments presented in the discussions.

Mr. George is to be thanked for clearly indicating the need for an automatic method of obtaining the transformation matrix T and hence has reemphasized the main purpose of the paper. His comments with regard to the numbering of the lines and nodes of a network is well taken and might be used to advantage by persons interested in trying to improve the method for developing a T matrix.

Dr. Kirchmayer and Mr. Wood have nicely shown the generalization of the T matrix to the complex field. They have further pointed out that the T matrix is the same as the connection matrix C as used in the work of Kron and Le Corbeiller.

The remarks of Mr. Bills are timely and the relation of his experiences has helped to fill in the background of the problem. The authors feel that certain problems may be better handled using the nodal analysis approach so that it is well to note that mutual inductances may be included in this analysis.

Mr. Schubert has indicated a method for obtaining the tree branches and links for an electric network. This could be used to solve the first part of the problem in a different manner. It can be expected that since there are many people who will become more interested in the T matrix and its application that even better methods will be forthcoming. The answer as to what is best will not be known until the ease of preparing data has been taken into account and the machine times for these methods are made available.

It has been the desire of the authors to keep the labeling of the network branches and nodes as flexible as possible. It seems that to require a program user to even parallel branches tends away from this desire. It is true that the computer is forced to do a relabeling in the authors' method but this is rapidly accomplished. Further, when any answers are printed such as for a short-circuit solution, the results are printed using the original labels assigned by the user.

In a previous discussion with Mr. Lantz the authors indicated some of the steps they were following in applying the T matrix to the solution of the short-circuit problem. Since that time a solution to this problem has been completed and the method has been described in a paper[1] to be presented at the Power Industry Computer Application Conference. It is hoped that this paper will answer the questions raised by Mr. Lantz.

In further answer to Mr. Bills, it should be stated that the *704* program using the method described in the paper is available for use by the electric utility customers on Analytical Department facilities in East Pittsburgh. The use of this program has been quite successful and has not failed to form the correct T matrix. In fact the logic of the program though it might seem complicated, is very straightforward. The reasoning is so clearcut that the method is applicable to all types of networks, even those not topologically mappable on a plane or sphere. An example of this type of network is shown in Fig. 8 of this paper.

Magnetic-Drum Components for High Storage Density

KYONGHI HONG
NONMEMBER AIEE

THE INFLUENCE of coercivity H_c and retentivity B_r of the recording medium has been studied by numerous authors in the field of magnetic recording. In 1946 Camras[1] considered the demagnetizing field of a bar magnet comprising the record medium and concluded that the reproduced voltage was proportional to B_r for long wavelengths and to H_c for short wavelengths. In 1947 Kornei[2] observed that a medium of high values of H_c/B_r gave better high-frequency response, while Holmes[3] concluded that in sound recording the ratio H_c/B_r should be greater than 0.1 and less than 1. Wetzel[4] also expressed a view similar to that of Camras on H_c and B_r and presented data supporting it in 1948. Begun[5] pointed out in 1949 that H_c was the most important factor in magnetic recording although he stated in 1955[6] that high H_c does not add materially to the medium's capability of retaining a short-wavelength signal unless B_r can be increased at the same time. In 1953 Daniel[7] reached the conclusion that as the wavelength approaches zero the playback voltage becomes proportional to $1/(1+B_r/H_c)$, while McGuigan[8] pointed out that the area recorded on the medium at the

Paper 58-929, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–27, 1958. Manuscript submitted February 10, 1958; made available for printing May 7, 1958.

KYONGHI HONG resides in Cambridge, Mass.

time of writing spreads out over an area larger than the area directly under the pole tip of the head, and that the extent of this spreading depends on H_c of the medium, without specifying how.

The resolving power of the playback head has been discussed by Begun;[8] Fuller, Husman, and Kelner;[9] and Hoagland.[10] Begun mentioned only the gap width as a factor determining the resolving power of the head and pointed out that the effective gap length is somewhat larger than the actual gap length, usually by about 50 to 100% for short gaps and down to 10% for long gaps. Fuller, Husman, and Kelner regarded the spacing between the head and medium as well as the gap length as factors determining the resolving power. Hoagland, on the other hand, believed the thickness of the medium as well as gap length and spacing to be the factors determining the resolving power.

Comprehensive formulas for maximum storage density of the medium, the playback voltage, and the resolving power of the head are derived in this paper to augment, correct, and resolve the conflicting viewpoints. The maximum storage density is the reciprocal of the minimum wavelength that the medium is capable of retaining. The wavelength is the velocity of the medium divided by the frequency of the writing current. Although these formulas should be applicable to any magnetic recording, audio or video, the main concern of this paper is the magnetic components of a magnetic drum where information is handled in binary digits (bits) and requires a distinction between only two magnetic states, erasing and biasing being unnecessary.

Maximum Storage Density

It is shown in the literature[11] that the second quadrant of a hysteresis loop can be expressed as

$$B/B_r = \frac{1+H/H_c}{1+(H/H_c)(B_r/B_s)} \tag{1}$$

where B is the induction, B_r the retentivity, H the magnetizing force, H_c the coercivity, and B_s the saturation induction as shown in Fig. 1. It is seen in this equation that B becomes B_r when H is zero, and H becomes $-H_c$ when B is zero. Westmijze[12] has shown that, in tape recording, the demagnetizing field of a longitudinally magnetized bar magnet comprising the tape can be expressed as

$$-H/B = -1/\mu = L/4\lambda$$

or

$$-H = BL/4\lambda \tag{2A}$$

where λ is the wavelength and L is the tape thickness magnetized uniformly throughout, while for perpendicular magnetization

$$-H/B = -1/\mu = (1-\pi L/\lambda)/4\pi$$

or

$$-H = B(\lambda-\pi L)/4\pi\lambda \tag{2B}$$

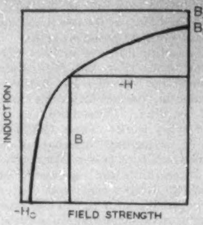

Fig. 1. Demagnetization curve

Combining equations 1 and 2(A) gives, after some rearrangement,

$$x = y(hy-1)/(y-1) \tag{3}$$

$$y = B/B_r$$

$$x = 4\lambda H_c/LB_r$$

$$h = B_r/B_s$$

x is plotted against y for various values of h in Fig. 2. L in Westmijze's derivation was the thickness of a uniformly magnetized tape. If the thickness of the tape be infinite from a practical point of view, then L may be regarded as the depth of magnetic penetration. In Fig. 2 it is seen that the linear relation between x and y holds when x is less than 0.2, or when h is equal to 1. When x is less than 0.2 the wavelength is less than half a mil, 1.27×10^{-3} cm (centimeter). When the wavelength is greater than half a mil and B_r is not equal to B_s the linearity fails and B depends on B_r. For the short-wavelength region which is the primary concern of this paper, the induction is

$$B = 4\lambda H_c/L \text{ or } 4\pi\lambda H_c/(\lambda-\pi L) \tag{4}$$

The relation between λ and L can be estimated as follows: if the tape is magnetized with both perpendicular and longitudinal components as is the case in practice, then the tape may be regarded as a chain of flux-closure domains as shown in Fig. 3. It is shown in the literature[13] that the relation between λ and L in Fig. 3 is

$$(\lambda/2)^2 = 2E_wL/K \tag{5}$$

where K is the anisotropy constant and E_w is the Bloch wall energy per-unit area, which is about 1 to 5 ergs/cm² for 180-degree-spin orientation. Equation 5 states that the magnetic penetration into the medium is proportional to the square of the wavelength.

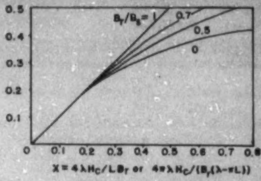

Fig. 2. Calculated curve of B/B_r versus $4\lambda H_c/\pi LB_r$ or $4\pi\lambda H_c/B_r(\lambda-\pi L)$ for various values of B_r/B_s

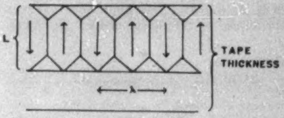

Fig. 3. Flux-closure domains of the medium

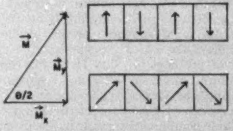

Fig. 4. Magnetization of medium with different angles θ and π between domains

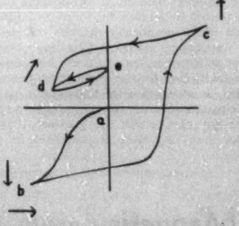

Fig. 5. Magnetic state of a point on a medium varied by recording and reproducing heads. Vectors illustrate the direction of magnetization

The flux-closure model in Fig. 3 gives some insight into the relation between λ and L, but it cannot be used for the study of the phenomena at the surface of the medium, for it has no poles. To cal-

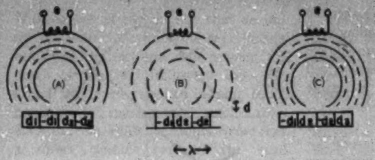

Fig. 6. Reading-head position for maximum (solid line) and minimum (dashed line) flux density. The mean circumference of the head is assumed constant

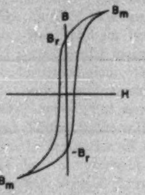

Fig. 7. Magnetic state of playback head varied by its position relative to record medium

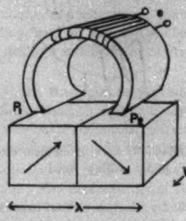

Fig. 8. Head-medium geometry

culate the maximum storage density of the medium, the tape is assumed to be magnetized as in Fig. 4. The energy content of the medium F_v, per-unit length of volume V, is

$$F_v = VB^2/8\pi\mu = (VL/32\pi\lambda)(4\lambda H_c/L)^2$$

$$= \lambda VH_c^2/2\pi L \qquad (6)$$

Since the magnetization of the magnetically hard recording medium takes place by the rotation of domains, angle θ in Fig. 4 is a measure of the magnetization, i.e., $\theta/\pi = B/B_s$, and the Bloch wall energy E_w' is proportional to the total change in spin direction θ. Therefore the sum of wall energies within unit length of the medium of cross-sectional area A with U bpc (bits per cm) would be

$$F_w = 2AUE_w' = 2AUE_w\theta/\pi = 2AUE_wB/B_s$$

$$= 2AUE_w(4\lambda H_c/LB_s) \qquad (7)$$

Increase in the storage density U can continue until F_w becomes equal to F_v. Such an equality gives the following formula for the maximum storage density

$$U = H_cB_s/16\pi E_w \qquad (8)$$

It can be readily shown that equation 8 is true for perpendicular magnetization also if $4\pi\lambda H_c/[B_r(\lambda - \pi L)] < 0.2$ or $B_r/B_s = 1$. If $H_c = 500$ oersteds, $B_s = 6{,}000$ gauss, $E_w = 2$ ergs/cm², then $U = 30{,}000$ bpc, and the minimum wavelength the medium is capable of retaining is $\lambda_c = 1/U = 0.3333 \times 10^{-4}$ cm.

Playback Voltage

A formula for playback voltage is of practical value in understanding the operation of magnetic recording. The medium is assumed to be demagnetized initially and is at the magnetic state, of **a** in Fig. 5. As a point on the medium comes under a writing head, its magnetic state is changed from **a** to **b** when the point is exactly under the leading edge of the gap. If B_s and ampere-turns of the writing head be great enough and if the medium-head spacing be negligible, the magnetic state at **b** is that of perpendicular saturation. The point is longitudinally saturated when it comes halfway between the gap edges, and varies from **b** to **c** when it comes under the trailing edge of the gap, and from **c** to **d** after it leaves the head. The value of B at **d** is less than B_r because of a demagnetizing field, but it becomes almost doubled to **e** when it comes under a reproducing head because the reproducing head reduces the demagnetizing field.

The magnetic state of the reading head (also called playback head or reproducing head) can be understood from Figs. 6 and 7. When the record medium moves under the reading head whose effective gap length is not equal to an integral multiple of the wavelength, the magnetic state of the head will be at $-B_m$ of Fig. 7 when it is at the magnetically asymmetric position of Fig. 6(A), at $-B_r$ when at the magnetically symmetric position of Fig. 6(B), and at B_m when at the magnetically asymmetric position of Fig. 6(C). In Fig. 6, position (B) is reached when the medium moves a distance of $\lambda/4$ from position (A). Position (C) is reached when the medium moves a distance of $\lambda/4$ from position (B). If the velocity of the medium be v, then the output voltage from the reading head is

$$e = -NAdB/dt = -NA(-B_r - B_m)/(\lambda/4v)$$

$$= 6vNAB_m/\lambda \qquad (9)$$

The last step is based on the assumption that $2B_r = B_m$, which is somewhat arbitary but does not hurt the generality. N is the number of turns of the reading coil wound tightly around the core at a symmetric position with respect to the gap, and A is the cross-sectional area of the core. For RZ (return-to-zero) coding, however, $e = 4vNA(B_r - B_m)/\lambda = -2vNA$-$B_m/\lambda$ also occurs.

The value of B_m is to be estimated by use of the model in Fig. 4 magnified in Fig. 8 where the effective gap length is assumed to be $\lambda/2$. The magnetic potential at P_1 is called V_1, and is determined by the surface distribution and volume distribution of the pole-strength density, namely,

$$V_1 = \int_s \frac{\sigma ds}{r} + \int_\tau \frac{\rho d\tau}{r} \qquad (10)$$

where σ is the pole strength per-unit area on the surface and ρ is the pole strength per-unit volume of the medium. V_1 is equal and opposite to V_2 at P_2. The model shown in Fig. 4 is that of opposing longitudinal bar magnets plus attracting transverse bar magnets at the same time. In case of a transverse bar magnet of length L and cross-sectional area $w\lambda/2$ magnetized uniformly along its axis, the magnetic moment of the bar is $\sigma Lw/2$, and the magnetic moment per-unit volume is[14]

$$\rho = M = B/4\pi = \sigma \qquad (11)$$

Combining equations 4 and 11 modifies equation 10 as follows:

$$V_1 = V = -V_2$$

$$= Mw(\lambda/2)[(1/d+L)/(d+L/2)]$$

$$= Mw\lambda/2d$$

$$= \lambda^2H_cw/\pi Ld$$

B (or M) is assumed doubled by the shunting effect of the reading head on the basis of the image method used by Wallace.[16] Therefore B_m can be expressed as

$$B_m = (2\mu V/l)[R_g/(R_c + R_g)]$$

$$= (2\mu gV/l)/(l/\mu + g)$$

$$= \frac{2\mu gH_cw\lambda^2}{ld(\lambda - \pi L)(l/\mu + g)} \qquad (12)$$

In equation 12 the cross-sectional areas of the gap and the core are assumed to be equal. The factor $R_g/(R_c + R_g)$ is in-

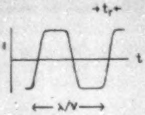

Fig. 9. NRZ current

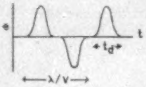

Fig. 10. Output waveform from NRZ coding

cluded because of the flux ϕ_c for the core is only part of the total flux ϕ such that $\phi_c = \phi[R_g/(R_c+R_g)]$, where R_g is the reluctance of the gap and R_c the reluctance of the core. μ is the permeability of the reading head, g the gap length, and l the magnetic path length of the core. Combining equations 9 and 12 now gives

$$e=\frac{12\lambda vNA\mu H_c w\sin(\pi g/\lambda)}{ld(\lambda-\pi L)(l/g\mu+1)}\text{ for perpendicular magnetization}\quad(13)$$

$$e=\frac{12\lambda vNA\mu H_c w\sin(\pi g/\lambda)}{ld\pi L(l/g\mu+1)}\text{ for longitudinal magnetization}\quad(14)$$

The factor $\sin(\pi g/\lambda)$ can be understood from Fig. 6(A). The gap length of the dashed line is λ and the flux through the reading head is zero because it is at a magnetically symmetrical position. A gap length 2λ is similar. In general, a gap length $n\lambda$ gives a zero field intensity, n being 0, 1, 2, 3, ..., as shown in Fig. 6(A). The maximum field intensity is obtained when $g=(n+{}^1/_2)\lambda$. This situation may be summed up by saying that the field intensity, and consequently the output voltage, varies as $\sin(\pi g/\lambda)$ and this explains the appearance of maxima and minima when the gap length is greater than one wavelength. Optimum gap length is $\lambda/2$.

In equation 13 for perpendicular magnetization the output voltage increases with the thickness L of the medium. In equation 14 for longitudinal magnetization the output voltage decreases when the tape thickness L is increased. In practice, however, the medium contains both longitudinal and perpendicular components. Therefore the output voltage is somewhere between the two expressions.

Resolving Power of the Reading Head

If the resolving power U of the medium is defined as the maximum storage density that the medium is capable of retaining as calculated in equation 8, then the the resolving power U_r of the reading head may be defined as the maximum storage density (also called packing density, cell density) that the reading head is capable of reproducing with full resolution.

It is shown in the literature[13] that the Bloch wall separating two adjacent domains oppositely saturated at 180 degrees has a thickness equal to $(kT_c/Ka)^{1/2}$, where k is the Boltzmann's constant 1.38×10^{-16} erg/degree; K the anisotropy constant which for a magnetically hard material is bH_cB_s, b being a constant close to 0.1; T_c the Curie temperature in absolute scale; and a the lattice constant which is a few times 10^{-8} cm. This thickness has to be multiplied by θ/π or B/B_s, because the record medium contains both longitudinal and perpendicular magnetization. If a numerical calculation of the ratio of this thickness to a wavelength is carried out, it turns out to be of the order of 10^{-2} for most recording mediums. Therefore the Bloch wall thickness cannot have much influence on the resolving power of the medium or the head.

A sequence of a nonreturn-to-zero (NRZ) current in Fig. 9 will have an output waveform shown in Fig. 10 as can be deduced from Fig. 6. In Fig. 10 a minimum wavelength λ_c that the reading head is capable of reproducing with full resolution satisfies the condition

$$\lambda_c/v=2t_d\quad(15)$$

The reproducing head can be looked upon as a pulse transformer whose rise time and fall time depend upon the winding inductance and the drive and load characteristics of the transformer. In Fig. 10 t_d is merely the duration time of the pulse. The primary winding is the magnetic flux from the record medium, and the magnetizing force H from a perpendicularly magnetized medium can be obtained from equation 12, namely

$$H=\frac{2gw\lambda^2H_c}{ld(\lambda-\pi L)(l/\mu+g)}\quad(16)$$

The general relation[16] between H and t_d for a constant rise time of the input pulse can be obtained from Kittel's equation of ferromagnetic resonance,[13] namely, $\omega_0=\gamma(BH)^{1/2}$, or $f=1/T=1/2t_d=\gamma H\sqrt{\mu}/2\pi$. It follows that

$$t_d=1.78\times10^{-7}/H\sqrt{\mu}\quad(17)$$

The relation between t_d and the rise time of the input pulse for a constant field intensity H can be given as a function of an optimum gap length as follows:

$$t_d=g/4v\quad(18)$$

Since neither equation 17 nor equation 18 is complete by itself, a unified expression for the duration time may be obtained by multiplying the foregoing two expressions of t_d and taking the square root:

$$t_d=2.1\times10^{-4}(g/vH\sqrt{\mu})^{1/2}$$

which, when combined with equation 15, gives

$$U_r=2{,}381(H\sqrt{\mu}/vg)^{1/2}\quad(19)$$

If $\mu=10^4$, $H=4.75\times10^{-2}$ oersted, $g=5\times10^{-5}$ cm, $v=600$ cm/second, then the resolving power of the head is $U_r=30{,}000$ bpc, and the minimum wavelength the head is capable of reading is $\lambda_c=0.3333\times10^{-4}$ cm.

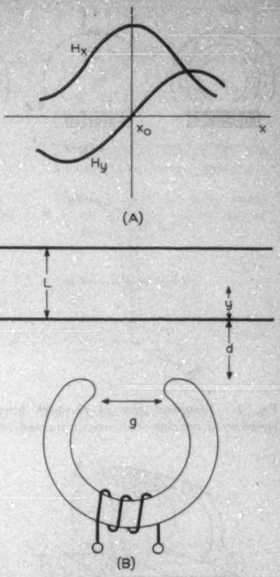

Fig. 11. Magnetic state of medium directly under writing head

Other Remarks

Formulas for the playback voltage in the short-wavelength region were previously derived by Camras,[1] Wallace,[15] Westmijze,[12] Daniel,[7,17] and Hoagland.[18] Camras believed that in the short-wavelength region the output signal increased when H_c or the reciprocal of the diameter of the recording wire was increased, although he did not explicitly show them in his equation. Daniel assumed zero spacing between the medium and the reproducing head in his derivation, but

Wallace was of the opinion that an imperfect contact between the reproducing head and the medium may account for much of the high-frequency loss. He found that even repeated lapping could not make the spacing much smaller than 5.8×10^{-4} cm, while Westmijze found that a direct contact between the head and medium was equivalent to an effective spacing of 3.6×10^{-4} cm. Westmijze's formula, like that of Wallace at unit permeability, was valid for both longitudinal and perpendicular magnetization according to his calculation. Demagnetizing fields were not considered by Wallace and Hoagland, but were studied by Camras,[1] Wetzel,[4] Westmijze,[12] and Daniel.[7] In the derivation of equations 13 and 14 for the playback voltage, the magnetic and physical characteristics of the head and medium as well as the demagnetizing fields of the medium were considered. They explicitly express the output voltage as a function of the reluctance, gap length, and spacing of the reading head as well as the coercivity of the medium independent of its retentivity.

As for the resolving power of the medium, equation 8 gives an answer to all the previous speculations on the maximum storage density of the recording medium.

Equation 19 points out that the field intensity and permeability of the reading head and the velocity of the medium contribute to the broadening effect of the output pulse, but it is also clear that the gap length of the reading head remains the most dominant factor determining the resolution. Improved gap designs have been attempted by several workers in recent years with success. Daniel and Axon,[17] in 1953 reported three different kinds of wedge-shaped gaps to give better performance in the short-wavelength region. Lufcy and Heath[19] reported in 1955 that Alfenol, whose initial permeability is 3,450 in contrast with 16,000 of Mo-permalloy, had an effective gap length about the same as its physical gap length. They obtained about 10^{-4}-cm physical gap by use of a beryllium-copper spacer. Hoagland[18] in 1956 recommended a pointed-type pole-piece design for a high storage density. Zenal[20] of the Radio Corporation of America reported in September 1956 that a video head resolving over 5,900 cycles/cm had been designed for color-television signals. In November 1956 Kornei[21] published data on a ferrite core head with a gap length of 7.9×10^{-5} cm which was spaced by silicon monoxide, and was capable of pulse-recording at densities up to 1,000 RZ pulses/cm.

The foregoing analysis of the maximum storage density leading to equation 8 was carried out from a magnetostatic point of view. If the same problem is approached from a dynamical point of view, the problem is that of diffusion. The degree of magnetic diffusion may have only a remote relation with skin depth $(\rho/\pi f\mu)^{1/2}$ where ρ is resistivity and μ permeability, but Karlqvist[22] believed that the magnetic field in the medium obeyed Fick's law of diffusion with ρ/μ as a diffusion coefficient. His graphs showed that a medium of low permeability should have less spreading (or diffusion) in longitudinal direction. The general results of his calculations, however, were similar to those published by Begun[23] in 1948. Their data are expressed in Fig. 11 and in the following equations

$$H_x=\frac{a(g+d+y)}{(d+y)[(x_0^2-x^2)^2+(g+d+y)^2x^2]}$$

$$H_y=\frac{a(x_0^2-x^2)}{(d+y)[(x_0^2-x^2)^2+(d+g+y)^2x^2]} \qquad (20)$$

where y is the depth in the medium measured from the surface of the medium, x is the longitudinal position, and a is a constant determined by the B_s and ampere-turns of the writing head. If the spacing d be negligible, the peak value of H_y may become equal to the peak value of H_x in Fig. 11(A). The situation here is similar to that of anomalous dispersion showing the index of refraction and absorption coefficient as functions of frequency,[24] or the reactance and resistance of a resonant electric circuit as functions of frequency. If the half-width of H_x curve is defined as the distance between the points at which H_x has half its maximum value, then it is approximately $(g+d+y)$ or the distance between the peaks of H_y curve. y may be equal to L, the tape thickness or the depth of magnetic penetration. For a high-density RZ coding, the velocity of the medium is selected by the relation $v/f=\lambda_c=2(g+d+L)+vt_d$. Solving this equation for v gives

$$v=2(g+d+L)/(1/f-t_d)$$

where t_d is the pulse duration time shown in Fig. 12, $1/f$ is the period of the RZ current, and λ_c is the minimum wavelength the medium or the reading head is capable of resolving. In NRZ coding, only the ratio $v/f=\lambda_c$ has to be considered.

Conclusions

1. The maximum storage density of a medium increases with its coercivity H_c and saturation induction B_s as shown in equation 8.

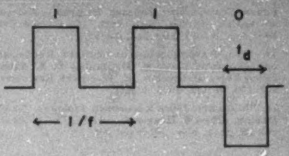

Fig. 12. RZ current

2. In a short-wavelength region, the playback voltage is proportional to the H_c of the medium and is independent of its retentivity B_r; see equations 13 and 14.

3. The resolving power of the reading head is mainly determined by the gap length, but is influenced by the field intensity and permeability of the head and the velocity of the medium also, as shown in equation 19.

Spectrum Analysis of Random Noise Generators

L. G. POLIMEROU
ASSOCIATE MEMBER AIEE

Synopsis: A method is introduced for evaluating the spectrum shape of random noise generators. This method uses only one selective filter and a variable chopper-carrier to select within a wide band, the frequency which is of interest. The random noise at the frequency selected is then squared and averaged over a sufficient length of time. This process being repeated at various frequencies yields the spectrum shape. The spectrum to be examined by the variable-chopper scheme is preshaped by a wide-band filter of known characteristic. The deviations of the output of the selective filter from the wide-band characteristic indicates the deviation of the original spectrum from a flat-shaped spectrum.

THE OBJECTIVE in this particular study was to determine the power spectrum of some type of random noise. For the sake of discussion, assume the existence of a particular type of noise, namely, a continuous stationary time series, i.e., a noise that has statistical properties which are invariant with time. Such noise will have two fundamental characteristics: an amplitude distribution, which specifies the relative probability that a given noise will occur; and the characteristic with which we are concerned, a power spectrum, which specifies the division of the noise power into frequency components.[1] A previous measurement of the first characteristic mentioned shows that the noise measured has an output characterized by a normal or gaussian distribution.

The probability distribution describes the intensity characteristics of the noise but does not describe the frequency characteristics called the power spectral density. The power spectral density may be calculated numerically as outlined by Tukey.[2] Briefly summarized, this procedure is: first, read the time-history record point by point; second, calculate the autocorrelation function of the data sampled by evaluating the integral $\int_0^T f(t)f(t+\tau)dt$ for various discrete values of time lag τ; and third, determine the power spectral density by taking the Fourier cosine transform of the autocorrelation function. However, there are two types of electronic analog equipment which might be used to determine power spectra: one type parallels the numerical process by first determining the autocorrelation function and then taking its transform to get the power spectral density; the other measures the spectrum directly by means of selective filters. A mechanized device providing a scanning electrical filter is described by Smith.[3]

Mode of Operation Analysis

The principle of operation involved in this analysis is based on the noise detection scheme which is used in the actual noise generator. In the noise generator, a frequency shifting procedure is used to produce noise in the frequency region from direct current to 40 cps (cycles per second). This noise is produced by utilizing a 450-cps electromechanical chopper to shift frequencies in a band pass approximately 100 cps wide, centered at 450 cps. The chopper multiplies the noise voltage alternately by plus one and minus one. This multiplication by a square wave results in frequency components consisting of sums and differences of the noise frequencies, and the chopper frequency and its various harmonics.

Similarly, a band of noise is selected in the frequency region of 350 to 550 cps in the noise evaluation set up. If a variable-frequency chopper is made to operate, in one instance, at 810 cps, it will produce frequency components consisting of sums and differences of all the noise frequencies in that band with 810 cps and the harmonics of 810 cps. Furthermore, if a very-narrow-band selective filter centered at 400 cps is used to select all 400-cps components formed as a result of the sums and differences of the noise frequencies and the chopper frequency and its harmonics, then those noise frequencies which would combine with the chopper frequency and its harmonics to yield components at 400 cps are 410 cps, 1,210 cps, 1,220 cps, 2,020 cps, etc. Among these, the only noise frequency available in the band of noise is the component at 410 cps. Therefore, while operating the chopper at a frequency of 810 cps, a 400-cps component will be formed with an intensity proportional to the corresponding frequency component at 410 cps. Furthermore, by varying the frequency of the chopper, in the frequency region at 750 to 950 cps, frequency components will be produced at 400 cps with an intensity which corresponds to the frequency components in the region of 350 to 550 cps respectively. The effect of varying the chopper frequency at discrete intervals throughout the range mentioned is comparable to having a set of parallel selective filters which are capable of passing a narrow band of frequencies at specified increments in the spectrum region to be examined.

Tests and Results

An examination of Fig. 1 shows a simplified block diagram of the noise generator and the measuring apparatus. The thyratron source output is shaped by a wide-band filter and then amplified. The amplifier output goes to a variable

frequency chopper, controlled by a signal generator through a power amplifier. The output of the chopper goes to a 400-cps selective filter. The output of the filter is squared and averaged with an electronic integrator.

A total of six separate tests were conducted to determine the shape of the spectrum. The frequency response of the filters used is given in Fig. 2. The first four tests lasted for 1 hour, 5 hours, 20 minutes, and 20 minutes respectively. The fifth and sixth tests, using automatic sequencing (Fig. 3) lasted for 5 hours and 8 hours respectively. In all of these tests, the integration period was manually controlled.

The first test consisted of performing three measurements at each designated frequency in the band from 350 to 550 cps, each frequency being spaced at 10 cps.

To do this, the chopper frequency was varied correspondingly over the range from 750 to 950 cps. Each measurement lasted for an integration period of 30 seconds. The test began by setting the chopper frequency to 800 cps, and proceeding in increments of 10 cps to cover the range from 800 to 950 cps. Then, the test continued again at 800 cps, and

similarly proceeded in increments of 10 cps to cover the range from 800 to 750 cps. The average value of $\overline{v^2}$ was computed from each set of three values at each designated frequency. The total time was one hour. A plot of the spectrum shape is then constructed showing the faired curves. The results of the first four tests are plotted in Figs. 4 and 5. Tables I through VIII contain data of all the tests, and Fig. 6 gives the cumulative distribution of test 5.

The second test was repeated at the designated frequencies in the same manner. However, each integration period lasted for 10 minutes, and only one measurement was conducted at each designated frequency. The total time was 5 hours.

Again, for the third test, only one measurement was conducted at each designated frequency. The integration period lasted for 30 seconds for each measurement. The total time was 20 minutes.

On the fourth test, three measurements were made at each designated frequency. The integration period lasted for 10 seconds each. The total time was 20 minutes.

The fifth test consisted of choosing only one frequency and using an integration period of 5 hours. To be able to do this, an automatic sequencing technique was utilized. This sequencing involved reversing the sign of the information at the input to the integrator whenever the output of the integrator reached ±100 volts. The output of the integrator is made to cycle between the limits of −100 volts to +100 volts. Variations in the period required to complete such a cycle were recorded to determine any nonstationary effects at the particular frequency. If it is desired, a long-time average of the energy in a narrow band of that frequency is also made available. In this case, a voltage of 140,000 volts was reached corresponding to the total number of sequencing cycles obtained at a frequency band centered at 450 cps in the noise output. Results of this test are found in Table V.

The sixth test consisted of varying the chopper frequency over the region from 800 to 900 cps in ten cps steps. The arrangement of the frequencies measured was constructed to represent the spectrum at three different intervals of time. During the first part of this test, $\overline{v^2}$ was evaluated only at the following frequencies: 400, 420, 450, 480, and 500 cps. The second part evaluated the following

frequencies: 410, 430, 470, and 490 cps. Also, the last part included the remaining frequencies: 440 cps and 460 cps. The results of the test are plotted in Fig. 7.

Discussion

In measuring the output of the noise generator which is being evaluated, certain fundamental limitations exist. Evaluation of the spectrum in its original region provides an easier analysis. An analysis of errors present is important. The type of noise being evaluated is also of interest.

FUNDAMENTAL LIMITATIONS

Certain fundamental limitations exist which necessitate determining the length of time necessary to establish accurate estimates of the statistical properties of the noise. Determining the spectrum shape at arbitrarily low frequencies requires an observation time which may become prohibitively long. Similarly, as the resolution of the spectrum becomes arbitrarily fine, the observation time again may become prohibitively long. This is a fundamental limitation and not a limitation imposed by technique. Bennett and Fulton[4] show the derivation of the equations for the length of time necessary to establish satisfactory estimates of the statistical properties of low-frequency noise. For instance, an equation which gives the time required to insure with 95% certainty that the mean value of the noise lies within $P\%$ of the true mean is

$$T=(2\times 10^4 N_0)/P^2\bar{e}^2 \text{ seconds}$$

where T is the time required in seconds, N_0 is the spectral density in volt² per cps, and $\bar{e}$ is the true mean value in volts. For example, to determine within an accuracy of 10% the mean value of the output of the noise generator which has a true mean value $\bar{e}$ of 0.05 volt and a spectral density, N_0, of 0.6 volt² per cps would require

$$T=\frac{2\times 10^4\times 0.6}{(10)^2\times(0.05)^2}=4.8\times 10^4 \text{ seconds}$$

or over 13 hours of integration time. Similarly, the time required to evaluate the spectral density with the use of an ideal narrow-band filter, i.e., zero attenuation for $f_0<f<f_0+\Delta f$ and infinite attenuation for all other frequencies, is shown to be approximately $T=(4\times 10^4)/P^2\Delta f$ seconds, provided $f_0>>\Delta f$.

MEASURING ORIGINAL SPECTRUM

To measure the spectrum shape of the noise output, and avoid lengthy observation periods, it is convenient in many instances to measure the region of the spectrum from which the low-frequency

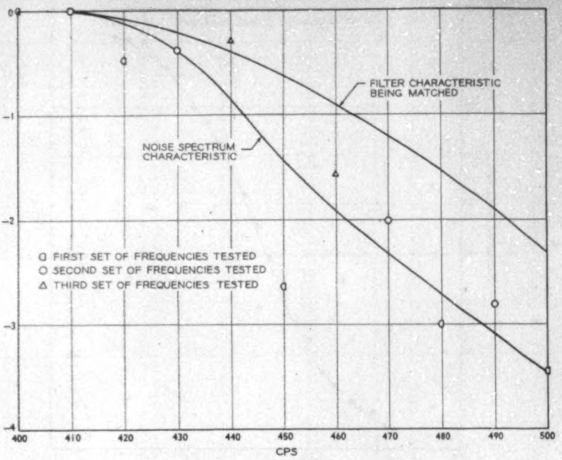

Fig. 7. Noise spectrum composite, test no. 6

noise was extracted, namely, 410 to 490 cps in this particular case. The reasoning used here is that the shape of the spectrum in the region of 410 to 490 cps will not change as a result of being translated to yield the low-frequency noise output so long as the frequency of the square wave or chopper is centered at the center of the tuned-amplifier band pass. This is exactly the way in which the noise generator was designed to operate. Therefore it may be assumed that if the region from which the noise was extracted is flat, and if the transfer function from the noise source output to the noise generator output is properly designed, then a flat band of frequencies varying from zero to 40 cps can be produced by the noise generator.

Now, the problem to be solved is to determine the shape of the spectrum in the region of 410 to 490 cps, which is a great deal easier than for zero to 40 cps. If the frequency region of 410 to 490 cps is the region of interest, a region somewhat larger than this must be examined so that edge effects (effects which result from the fact that the narrow-band selective filter meausres more than just a narrow frequency band centered at the frequency being measured) are lessened. In this set-up, a region over twice as large as the region of interest was selected as that to be examined for most of the experiment, namely, the frequency region from 350 to 550 cps. Having determined the wide-band filter characteristic, Fig. 2, any deviation of the noise source output in the region examined, from a flat frequency shape, will cause a deviation of the noise shape from that of the wide-band filter characteristic, i.e., the shape of the wide-band filter characteristic can be reproduced by the noise passing through it only if the shape of noise spectrum is flat. Again, this may be seen from the fact that at the output of the wide-band filter, the noise spectrum is the combined characteristic of the input noise spectrum operated upon by the wide-band filter characteristic, and since the filter involved acts as a known linear operator, then the deviation of the combined characteristic of the noise from the filter characteristic itself determines the deviation of the input noise spectrum from a flat-shaped spectrum. Therefore, it may be assumed that if a variable-frequency narrow-band selective filter is used to examine the noise at the output of the wide-band filter at various frequencies, then the output of the narrow-band selective filter will reproduce the wide-band frequency characteristic only if the noise input to the wide-band filter is flat-shaped. Furthermore, the deviation from reproducing the wide-band filter characteristic is the same deviation of the wide-band filter input noise shape from a flat spectrum.

With this basic material in mind, it remains to translate the frequency component which is to be measured with a single fixed-tuned narrow-band selective filter. Since, as indicated earlier, the process of chopping an electric noise signal by using an electromechanical chopper produces sums and differences of all frequency components present in the noise with the chopper frequency and its harmonics, then by limiting the frequencies to be examined, linear detection can be obtained. Also, a frequency component can be produced at 400 cps, proportional in intensity to any frequency component to be examined, by varying the chopper frequency, in such a way that its frequency minus 400 cps results in the frequency component to be measured. Once more, this is to say that a frequency component is produced at 400 cps which is proportional to the frequency component f_i being examined, f_c (chopper-frequency) minus f_i produces the 400-cps component. Also, since no other frequency in the noise range being examined, except f_i, produces a 400-cps frequency component with any one particular f_c, this detection scheme is essentially linear.

TYPES OF ERRORS

There are many possible sources of error in an experiment of this type, and each must be examined and minimized. Among these sources of error may be included arcing of the chopper contacts and contact bounce, pickup noise in cabling due to stray fields, drift in d-c amplifiers and integrators, level of signals sent to multipliers being limited, and noise originating in the multipliers and nonlinearities introduced by squaring the noise in the multipliers, and errors due to manual timing procedures.

To counteract the first source of error the noise voltage was amplified before reaching the chopper and a small-valued capacitor was used to minimize arcing. Also, the chopper driving-voltage level and shape must be controlled to give minimum bounce. Another factor is obtaining the proper matching impedance for the transformer used to convert from a single-ended amplifier to the balanced operation of chopping.

To prevent adulteration of the noise from stray fields, the voltage level was amplified to a high level before sending the noise signal over wires of any length. Also, the properly shielded wires were used when sending the noise voltage over the 100-foot cable to the computer console and from the console to the diode-electronic multiplier.

Drift was combatted in the amplifiers by using a minimum number of selected amplifiers. Drift in the integrator was reduced by using one of several specially converted integrators giving extremely low drift over periods in terms of hours. Also, by the use of automatic sequencing, alternating the direction of integration tended to average out such drift.

Also, as the frequency of the signals supplied to d-c amplifiers increased, limiting occurred due to output capacity of the d-c amplifier, which meant that voltage levels from the amplifiers could not exceed 30 volts without overloading. This in turn meant that peak voltages of more than 9 volts could not be obtained from the multipliers, since the multipliers produce an output voltage XY/100. As a result, since the signal output of multipliers is limited to low voltages, the accuracy involved is highly sensitive to drift and errors due to nonlinearities of the multiplier. However, again if automatic sequencing is used, even these errors are diminished. Also, where trouble in squaring high-frequency noise is involved, another means is available under certain conditions. If the noise is normally distributed and the mean value of the noise can be eliminated, then the mean-square value of the noise may be inferred from the average of the positive (or negative) values of the noise voltage according to the equation $\overline{v^2}=2A^{+2}$, where A^+ is the average value of the positive values of the noise.[4] A^+ can be conveniently determined by rectifying the noise and then integrating. This method has excellent frequency response and can yield considerable accuracy.

Finally, manual determination of increments of time in the order of less than one minute can also add notable error. Precise timing mechanisms would be required to turn the computer on and off to eliminate this type of error.

Several tests were conducted from time to time to look at the summed effects of a combination of several of these errors. Observing the noise level at the output of the amplifier following the chopper showed a fairly good response, so that the noise level, with the noise source connected, was more than 20 db above the level with the noise source disconnected and the lead to it grounded. Also, the integrator output was examined regularly, with the input to the cable from console to diode-electronic multiplier grounded at the console, and the output at the integrator represented an error never more than 2% of the actual test reading.

TESTING FOR NONSTATIONARY TIME SERIES EFFECTS

The fifth test was conducted specifically over a long integration period to discover variations of the statistical properties of the noise with respect to time. A statistical analysis of the data obtained from this experiment shows that only 14 out of 362 measured values fall outside of the $\pm 2\sigma$ region for this data, thus showing the validity of the fact that with 95% certainty, the data shows less than ±13% variation for a period of 5 hours. For shorter periods, or with an occasional adjustment of level, smaller variations would result.

Conclusions

An examination of this experiment shows the following facts: The noise presents a stationary time series for periods of more than one hour. The spectrum shape in the region of 410 to 490 cps representing the noise generator output frequency of zero to 40 cps is flat within ±1 db. Improvement in the measuring technique may be obtained by automatic timing circuits.

An Electronic Feedwater Control System for the Experimental Boiling Water Reactor

R. H. MORSE
NONMEMBER AIEE

R. N. BREY, JR.
NONMEMBER AIEE

THE feedwater (FW) system for the Experimental Boiling Water Reactor was designed for utmost flexibility to accommodate many different experiments and procedures scheduled for this facility now in operation at the Argonne National Laboratory. Design criteria called for control of level from either the hotwell or the reactor vessel and ability to switch from simple single-element control (level control adjusting the main FW valve) to 2-element control, using either steam flow (SF) or FWF (FW flow) as the second element, to 3-element control using level, FWF and SF. Further, all of these functions had to be adjustable as to their worth, one to the other, and the final resultant signal to the FW control valve had to be adjustable as to proportional band, reset (integral), and rate action (derivative), to allow 3-function control.

As may be seen from the over-all plant flow diagram in Fig. 1, the steam cycle is a simple single cycle enclosed with two main storage capacities for water, i.e., the condenser hotwell and the reactor vessel. Thus, neglecting leakage of steam and water from the system and under a steady steaming rate, FWF is equal to SF on a mass flow basis. Thus, any changes in SF or FWF or both will cause level changes in the hotwell and in the reactor vessel. The power output of a reactor of this type, assuming it is hot, critical, and boiling, is affected by FWF and FW temperature. Reactor power increases if FWF increases or if FW temperature decreases, thus a method of limiting the speed with which the FWF water can be changed is desirable since any large fast flow changes can have serious transient effects on reactor power. An electric valve drive mechanism has this desirable

feature plus adjustability of maximum *dw/dt* that can be introduced.

Rapid and large changes in level in the reactor vessel can also affect reactivity and thus power level by temporarily affecting bubble formation and the boiling heat transfer coefficient due to the head change, thus it is desirable to hold level as close as possible to set point even during large changes in steaming rate without large fluctuations in FWF. In order to minimize upsets to reactor level, this system was designed so that the SF response action can be delayed to compensate for the effects of "shrink" and "swell" which take place during load changes. This effect is inherent, either in conventional boilers or in boiling water reactors. As steaming rate is increased the additional steam bubble formation replaces saturated water in the vessel. This causes decreased over-all density and a rise in level in the vessel. The reverse is present when steaming rate is decreased. To appreciate this fully, consider the water within the reactor vessel to be at saturation pressure and at normal steaming level but with no steam being formed. Now consider the formation of steam bubbles around the core. It becomes apparent that for each steaming rate a different weight of water is present in the reactor vessel, assuming the level is held constant. In order to maintain this constant level, on an increase of steaming rate, an amount of water must actually be removed from the reactor vessel as steam. On a decrease in steaming rate, water must be added.

The SF delay network was designed with proper flexibility so that on changes in steaming rate the water flow could be maintained constant for a period of time and then moved to the proper value, or the water flow could be temporarily moved in the opposite direction to SF, depending on which adjustment tends to produce the maximum of stability in the process. The SF delay, therefore, permits the control action to decrease water flow momentarily on an increase in load and increase water flow momentarily or a decrease in load.

The system as designed appeared to require the considerable complexity which is present. This was caused by the number of unknowns in a project of this nature. Future systems may be simplified by substitution of valve position for FWF, and megawatts, or some other readily available measure of output, as an antici-

pating signal rather than SF-FWF ratio. These modifications will leave the basic system unaltered but employ simplified measuring techniques.

Components of the System

The major components of the control system, as seen in Fig. 2, are electronic SF, FWF, reactor level, and hotwell level transducers; SF, FWF, reactor level, and hotwell level Speedomax recorders; mixer; servoamplifier; and electric FW valve drive mechanism and valve assembly.

Transducers

The transducers for flow and level are differential-pressure-actuated electronic units. The meter body unit converts the linear mechanical motion of stainless-steel differential bellows into a rotary-motion torque-tube output. This torque-tube motion displaces a balanced beam in the transmitter unit, changing current in an electronic oscillator circuit. Current changes of 0.5 to 5 milliamperes are employed in both the output and the feedback (force balance).

Recorders

The Speedomax recorders accept the current output from the transducers by looking at a 50-millivolt d-c drop across a precision 10-ohm resistor. Since the transducers have an output proportional to differential pressure and since differential pressure varies as the square of the flow rate in pounds per hour, it is necessary to employ circuitry in the flow recorders which extracts the square root of the input and automatically adjusts recorder amplifier gain in order to have a linear scale and to retransmit linear intelligence to the control network. (This network computes the action to be taken from the linear signals received and is designated as the mixer.)

The control point as indicated by a red pointer on the level recorder can be varied over the 40-inch range of the recorder scale by means of a control point setter knob. The range is calibrated −20 to 0 to +20 inches of water. The control system then functions to keep the level of the reactor vessel or hotwell, as selected, at the control point setting. Since the total span of possible level measurement and control in the reactor vessel is 96 inches, a coarse zero setter is provided on the reactor vessel level recorder which permits adjustment of the zero point of the recorder between 20 and 76 inches of level.

Mixer

The mixer includes the necessary circuitry to provide the required control action from either the error signal developed between water level and its set point ($L-L_0$) and a signal proportional to FWF-SF ratio. Included in this mixer is a delay network which times the FWF-SF ratio response to compensate for swell and shrink on load changes. This mixer also provides control functions of proportional, reset, and rate actions. To provide complete flexibility, each function is adjustable over a wide range. In the event that any of these functions are not desired, they may be cut in and out by means of selector switches. The unit contains the following control adjustments:

SF response cut-out switch.
Water flow response cut-out switch.
Master level control selector switch.
SF proportional band adjust.
SF time-delay adjust.
Water flow response-time adjust.
Valve drive proportional band adjust.

As mentioned in the foregoing, the intelligence to the mixer unit originates from bridge circuitry which contains retransmitting slide wires from the FWF, SF, and level recorders and the FW valve drive mechanism.

When the control is in full 3-element operation, the retransmitting slide wire on the valve drive unit output shaft provides an instantaneous velocity feedback which is progressively "washed out" to be replaced by the exactly metered water flow feedback. This system, therefore, compensates for process and metering lags and any nonlinearity in the valve characteristic.

Control Amplifier

The control amplifier can be considered as consisting of three basic parts; the converter, the voltage amplifier, and the relay section. It is essentially a polarity-sensitive detecting element. Thus, a d-c signal of a given polarity resulting from mixer unit unbalance will, when processed, energize the relay coil and actuate the valve drive motor with its accompanying feedback slide wire to drive the bridge in the direction of rebalance. Two relays are provided in the amplifier, one operating from a negative signal and the second from a positive signal.

Motor Valve Drive Unit and FW Valve

The final control element in the system is an electrically operated FW valve with stainless-steel body and internals. Stainless steel is used to prevent corrosion. The valve is sized for correct throttling action and internals are selected to characterize the valve action as nearly as possible to give a straight-line relationship of flow rate versus valve stem position. A special leak-off connection is supplied to collect any leakage from the packing when the plant is operated with heavy water.

A mechanical linkage converts the rotary motion of the electric drive unit to a linear motion to drive the valve stem. Further adjustments can be made in this linkage arrangement to characterize the valve under plant operating conditions.

The drive unit itself has two worm-gear reduction stages driven by a 3-phase reversible motor. Position transmitting slide wires and travel limit switches are included in the assembly. The double-reduction worm-gear arrangement provides a self-locking feature which prevents the unit from being "back driven" when de-energized. The position-indicating slide wires provide indication of true valve position of the control panel and feedback to the control network.

Operation of the System

Single-Element Control

Fig. 3 outlines the simple proportional position control circuitry where the FW valve position is maintained proportional to reactor level. Note that in the bridge circuitry above deviation voltage e is designated by a circle which is used in all following figures for purposes of simplicity. S_1 represents a slide wire mounted in the recorder or drive unit. Any motion of the slide-wire contact from its mid-position produces an error voltage.

The control system compares the error signal from the level deviation circuit e_1 and drive unit slide wire e_2, pro-

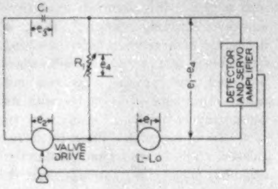

Fig. 4. Single-element proportional plus reset action control

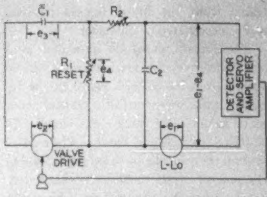

Fig. 5. Single-element proportional plus reset plus rate action control

ducing a corresponding error signal (e_1-e_2) to the detector and amplifier which will result in repositioning the drive unit until (e_1-e_2) is zero.

The relative travel of the drive unit with respect to the level error is the proportional band of the system. This is readily adjustable in the bridge circuitry by the relative settings of S_2.

Fig. 4 indicates the addition of reset action to this circuitry by a simple modification. This comprises the addition of capacitor C_1. This capacitor makes it impossible for the control bridge to be balanced when there is any level deviation e_1 except by a slow and continuous movement of the drive unit e_2 which produces a charging current on capacitor C_1 and a voltage drop e_4 on R_1.

The time constant of network R_1C_1 is adjusted to match the response time of the process and produces a rapid and steady return to control point on any upset in level.

The reset speed is proportional to deviation since as e_1 increases a larger charging current on C_1 results because e_4 must be larger. However, for a given level deviation the speed of valve action remains constant since the rate of increase of e_3 is constant because $E=Q/C$.

Rate action is available although not generally required on this porcess. Rate action operates to add a further increment of valve action as a function of the rate of change of level.

This action is provided by the addition of R_2 and C_2 as shown in Fig. 5. Rate action is produced if the rebalancing voltage e_4 is attenuated.

TWO-ELEMENT CONTROL

Fig. 6 illustrates the substitution of FWF for valve position as the output of the circuit, retaining valve position as a velocity feedback to compensate for process and metering lags and nonlinearities in the process.

An error signal e_1, representing level deviation, is detected and amplified, moving the valve to a new position. The change in voltage e_2 produces a charging current on C_3 which passes through C_1 and develops a voltage e_4 on R_1, rebalancing the amplifier. As the change in FWF is detected (e_5), the charging current on C_3 decays and is replaced by e_5. The time constant of R_3C_3 is selected to match the process and metering lags encountered. Therefore, the valve position feedback "washes out" and is employed only as a velocity feed back.

The reset action in the circuitry operates as described in the foregoing. A previously mentioned, the foregoing functions are completely adjustable and may be cut out if so desired.

THREE-ELEMENT CONTROL

Fig. 7 illustrates the addition of SF-water flow ratio anticipation to the circuit, with its accompanying delay network.

A voltage e_6 is developed across the bridge by the metered SF. Any deviation between SF and water flow (e_6-e_5) causes a charging current to flow through C_1 and develop a voltage e_4 on R_1. Thus, the amplifier repositions the valve drive mechanism, which in turn changes the FWF until the (e_6-e_5) error voltage is eliminated. This action eliminates any deviation between SF and water flow.

To compensate for swell and shrink of water level during load changes, the network R_4 and C_4 has been added to delay the action of the SF-water flow error (e_6-e_5) by stabilizing e_6 for a definite period of time after a change in SF.

Advantages of Electrical Control

1. *Permanent Calibration.* In the electric system, where resistors and capacitor values can be readily controlled, the control-response dial calibrations can be accurately determined and maintained constant.

2. *Linear Response.* In the electric system, a linear rate of reset is available over the entire valve range.

The same is true also for rate-time calibration, as the electric system is unaffected by compressibility effects.

3. *Readily Serviced.* Electric systems lend themselves to unitized designs in which various units or components can be plugged together or separated quickly for servicing.

4. *Transmission Lag.* Electric transmission is not subject to lag. This is of particular importance on fast-responding processes such as flow control.

5. *Flexibility.* The electric system is extremely flexible from the standpoint of combining other features into a standard control system.

6. *Building Integrity.* In the Experimental Boiling Water Reactor, the all-electric control system adapted itself readily to maintenance of building integrity. The containment philosophy required that a minimum of piping or tubing penetrations be made in the primary plant containment vessel. The rubber insulation was vulcanized to the wires to

195

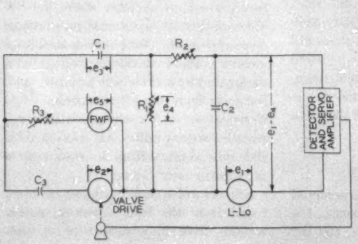

Fig. 6 (left). Two - element proportional plus reset plus rate action control

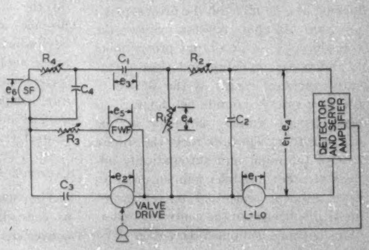
Fig. 7 (right). Three - element proportional plus reset plus rate action control



prevent gas streaming along the conductors. Wires were then brought out through a plastic-filled trough.

7. *Bumpless Transfer.* Transferring system from manual control to automatic control and vice versa is performed readily by the operator with no rebalancing operation of any type. The control system remains continuously in balance so that any transfer is "bumpless." Should transfer from manual to automatic control be made with the process away from the control point, reset action brings the process rapidly and smoothly to control point with no proportional action bump. (The detailed circuitry showing how this is accomplished is not covered in this paper.)

Main Coolant Instrumentation for High-Performance Pressurized Water Reactor Power Plants

L. C. NOYES
MEMBER AIEE

Synopsis: New pressurized water reactor designs are obtaining higher efficiencies and smaller physical size by operating primary coolant loops at higher temperatures and pressures. Since the ultimate temperatures and pressures are limited by the critical point of water and instrument errors, highly accurate process-type instrumentation is required and the instrument engineer becomes an important member of the reactor design team.

A brief résumé of the design requirements for pressurized water reactor temperature, pressure, flow, and liquid-level instrumentation is discussed. The goals to be met by the development are followed in logical order by a discussion of the means chosen to achieve them. Because the primary use of high-performance pressurized water reactors at present is for ship propulsion, the requirements for reliability and long life under vibration and high shock have forced the evolution of self-balancing magnetic-amplifier circuits for process-type measurements as well as new detector designs.

In conclusion, performance data are presented on the measurement set errors.

THERE are two reasons for better instrumentation on a nuclear power plant:

1. To obtain greater plant efficiency and higher power output for a given reactor plant design.

2. To reduce the over-all plant investment by reducing the size and complexity of other plant components such as reactor core, piping, pumps, steam drum, etc.

For ship propulsion reactors, highest plant efficiency and greatest power output from a given reactor plant design are the most important. Generally, a decrease in efficiency means a larger increase in the size and weight of components such as reactor core, coolant pipes, pumps, etc., to obtain the same power output. Conversely, a relatively small increase in over-all plant efficiency can mean significant savings of weight and space which can be devoted to the purpose for which the ship is being built, be it merchantman or warship.

The primary use of pressurized water reactor power plants to date has been for ship propulsion, and the coolant instrumentation described in this paper was developed especially for shipboard use. However, the functional requirements for instruments of both shipboard and land-based power plants are the same, and while the physical construction might change, the principles of operation are equally advantageous for land based use.

The design of a pressurized water reactor power plant is too highly complex to even outline in this paper and has been reported in the literature.[1–6] However, it should be noted that the plant is an interdependent system and the selection of primary and secondary operating temperatures and pressures is a compromise of many conflicting factors. To achieve highest thermal efficiency, most effective utilization of nuclear fuel, and lowest cost for steam plant equipment, secondary steam system pressure and temperature should be as high as possible.

The primary coolant temperature, pressure, and flow are determined by such factors as size and cost of core, pumping power required, and steam-generator size and cost. The cost of primary system components increases with pressure and 2,500 psi (pounds per square inch) represents about the highest practical design pressure at present. The nominal operating pressure for a 2,500-psi design pressure has been 2,000 psi. At 2,000 psi the saturation temperature of water is 636 F (degrees Fahrenheit). With more accurate temperature and pressure instrumentation of the type described here, safety margins required to protect for possible instrument errors are reduced and the operating pressure may be safely increased to 2,200 psi with an increase of saturation temperature to 650 F.

Thus a decrease in measurement errors means an increase in power output for a given plant design, and the instrument engineer becomes an important member of the reactor design team.

Functions

The measurement of nonnuclear quantities on the main coolant loops of a typical pressurized water power plant are shown in Fig. 1. These include numerous temperatures and pressures as well as flow in the loop piping and level in the pressurizer vessel. Each of these measurements requires a local indication of the measured variable at the main coolant instrumentation cabinet as well as a remote indication on the main reactor plant control benchboard and possibly other locations such as the main coolant charging station. In addition to direct indication of the quantity, many of the functions initiate alarms, slow rod drivedowns, or scram the reactor through signals to the

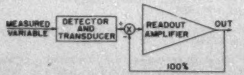
plant safety system when any of the quantities indicate that the measured quantity is out of control. Some quantities also operate either direct-acting on-off controls or provide a direct current proportional to the measured variable for rod control.

Design Requirements

The environmental and other design requirements for naval reactor instrumentation have been codified in *MIL-N-19900*.[6] A brief abstract of some of the more important points is included in Table I and this paper describes instrumentation built specifically to fill these requirements.

Vacuum tubes, motors, and most types of moving parts have been specifically prohibited except where absolutely essential in detectors and indicators since maximum reliability under these difficult operating conditions is required. The prohibition against moving parts and the requirement of highest possible accuracy under widely varying temperature, voltage, and frequency naturally lead to the selection of all-electric self-balancing systems using 100% negative-current feedback; see Fig. 2. Self-balancing systems of this type are current generators and provide all of the advantages of current output telemetering. This choice has been well justified since the systems have performed equal to or better than specification limits and far outperformed open-loop voltage output systems.



MEASURED VARIABLE
DETECTOR AND TRANSDUCER
READOUT AMPLIFIER
OUT
100%

Fig. 2. Self-balancing measurement system

In order to obtain maximum versatility and economy of manufacture, the measurement sets were split into four modular building blocks. These building blocks are:

1. Readout amplifier.
2. Bistable amplifier.
3. D-c constant-current source.
4. A-c regulator amplifier.

To aid in understanding the operation of the measurement sets, the operation of the four building blocks is described first, then the combination of the required blocks and the necessary detectors into a measurement set are described.

Since a number of proportional and on-off control functions may be required from a single measurement as well as local and remote indication, it was decided to standardize on a universal 0 to 5-ma (milliampere) d-c output from the readout amplifier into a maximum load of 5,000 ohms regardless of quantity being measured, or the range or span of measurement. This permits the use of one standard design of indicator and bistable control. It also provides sufficient power to operate as many indicators and on-off controls as required in addition to providing a current proportional to the measured quantity. In some cases as many as four indicators and six controls are operated from one measurement.

Readout Amplifier

For the readout amplifier a self-balancing magnetic amplifier was developed. It has two center-tap push-pull full-wave self-saturating stages in a 100% negative-current feedback-type (self-balancing) circuit. Magnetic amplifiers of this general type have recently been described

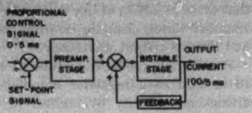

Fig. 4. Block diagram of bistable amplifier

by Geyger[7,8] and others.[9-11] A unique feature of this circuit is that the comparison between the output current I_L and the input signal always takes place ahead of the first magnetic-amplifier stage and only the difference signal I_c is fed to the input-stage control winding. (This puts any change in control-winding resistance or first-stage core characteristics inside the feedback loop, and zero drift is held to a minimum.)

The circuit offers several advantages:

1. When voltage comparison is used, as in Fig. 3(A), the negative-feedback voltage $E_K = I_L R_K$ is in series opposition to the signal voltage E_s, thus increasing the effective input impedance of the amplifier 200 to 300 times. Thus the readout amplifier presents a high-impedance load to the signal source and acts like an ideal voltmeter.

2. When current comparison is used, as in Fig. 3(B), the negative-feedback current I_L is in parallel opposition to the signal current I_S, reducing the effective input resistance of the amplifier 200 to 300 times. Now the readout amplifier presents a low-impedance load to the signal source and acts like an ideal galvanometer.

3. The effective internal impedance of the output circuit is much higher than its original value without feedback and the amplifier is essentially insensitive to changes in load resistance.

4. The output current I_L remains proportional to the input control current I_c and the amplifier is substantially insensitive to wide variations in temperature, voltage, and frequency.

For satisfactory closed-loop operation the time constant of the first stage is made as long as possible and the time constant of the second stage as short as possible. This has resulted in an amplifier having high open-loop gain, low zero drift, and complete freedom from instability under all environmental conditions.

Moderate precautions in matching magnetic core and silicon rectifier characteristics have resulted in a rugged amplifier capable of operating over the entire range of ambient conditions given in Table I with a zero drift referred to the input of less than $\pm 10^{-9}$ watts and an over-all accuracy of ±0.5% of full scale.

Standardizing on this readout amplifier design has permitted the elimination of separate voltage-regulated power supplies for the instrument cabinets and gives maximum economy of manufacture.

Bistable Amplifier

The alarm and on-off control functions provide a special problem. Here it is desired to initiate the alarm or control action when the measured variable reaches a predetermined value. Since the proportional control current output from the readout amplifier had been standardized at 0 to 5 ma d-c, it was possible to develop a bistable amplifier with a single input current range.

The bistable amplifier is an all-magnetic static switching element[12] designed to give a step change in output signal when the input signal reaches an accurate predetermined value. For use with the reactor safety system, it delivers a nominal output of 100 ma d-c into a 265-ohm load while the variable is in the "safe" control range. When the prescribed limit is reached the bistable stage "trips down" to less than 5 ma signaling the change to the reactor safety system. To ensure fail-safe operation, no relay is used because of the danger of relay malfunction under high shock or vibration, and the safety system is always energized when the variable is in the safe control range. Thus a power failure or open circuit in the bistable unit will initiate the protective action.

For the less critical on-off control and alarm functions, a relay is permitted. The bistable amplifier is identical with that just described except that the output current energizes the relay coil instead of the safety system. The relay is always energized when the variable is in the control range. Thus a power failure to the bistable unit drops out the relay causing the alarm action or securing the control function and the amplifier is again fail-safe.

The bistable amplifier[13] is basically a 2-stage magnetic amplifier consisting of a center-tap push-pull linear amplistat[14] preamplifier and a center-tap single-ended bistable amplistat output stage; see Fig. 4. To give the output stage its bistable characteristic, shown in Fig. 5, external positive feedback has been employed. For highly accurate switching the positive feedback is adjusted until the difference between the trip-up and trip-down points is made as small as possible and both occur very close to zero.

The preamplifier continuously compares its input signal to a preadjusted set-point signal. When the sum of the two signal ampere-turns is approximately zero it

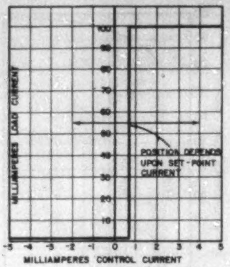

Fig. 6. Bistable amplifier control characteristics

drives the bistable stage through the trip point; see Fig. 6. The set-point bias is obtained from a Zener diode reference and is applied to the preamplifier in a direction opposing the readout amplifier proportional control current. By reversing the direction of the two control currents in the preamplifier and the direction of the signal from the preamplifier to the bistable stage, the bistable stage may be made to trip down on either an increasing or decreasing proportional control current from the readout amplifier. Thus the same bistable amplifier may be used for either a high or a low control and still maintain the proper fail-safe characteristics.

Since the portion of the preamplifier control characteristic shown in Fig. 7 represents only about 1% of the maximum proportional control current, the preamplifier is saturated most of the time. Therefore the gain of the preamplifier stage is high about the set point and the signal required to trip the amplifier is only about 4×10^{-8} watts.

Tests have shown the bistable amplifier to have a set-point accuracy of better than ±1% and a trip time of less than one second under the entire range of environmental conditions including high shock.

Where necessary, modifications of the amplifier gain and positive feedback may be made to provide variable or wide deadband characteristics. Also, additional input control windings may be provided for use where the coincidence of two or more signals is required to initiate a trip action.

D-C Constant-Current Source

The d-c constant-current source amplifier shown in Fig. 8 is a 2-stage self-balancing magnetic amplifier similar to the readout amplifier. It is used to supply a constant 400 ma into a maximum load of 52.5 ohms consisting of a temperature bridge and a feedback resistor. Since the bridge output voltage is directly proportional to the current applied to it as well as to the resistance thermometer temperature, it is imperative that the d-c constant-current source be of the same high-quality design as the readout amplifier.

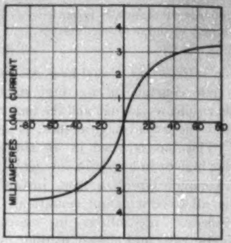

Fig. 7. Preamplifier-stage control characteristics

As shown in Fig. 8, a Zener diode is used as the reference signal source E_{ref} which is compared with the feedback voltage E_K. The difference of these two voltages is fed to the first stage as a control signal resulting in the control current I_c.

The output stage is a center-tap single-ended amplistat biased to operate at about 400-ma output for zero-signal input. Biasing the output stage in this way reduces the range of operation for the input stage, greatly simplifies the regulator operation, and takes maximum advantage of the high gain of the input stage around zero input.

Tests on amplifiers of this type have shown that any constant preset current can be held to a regulated accuracy of ±0.5% including the drift of the reference diode over the entire range of environmental conditions.

A-C Regulator Amplifier

The a-c regulator amplifier shown in Fig. 9 is similar in operation to the readout amplifier and the d-c constant-current source previously described, except that its output is a-c instead of d-c. It is used to maintain a constant current in the primary of the movable core transformers (MCT) of the flow and liquid-level measurement set detectors. The primary of MCT_1, with its core fixed in place, is connected in series with the amplifier load MCT_2. Its output voltage E_K is rectified and compared with a reference voltage E_s obtained from a Zener diode. This extra MCT_1 is necessary to correct for the waveform errors that occur in MCT_2 as line voltage to the amplifier varies, changing its firing angle and thus its output waveshape.

The d-c/a-c quotient amplifier in Fig. 10 is used as a regulator amplifier to divide one quantity by another in the following manner.

Let $I_s = X$, $I_K = YI_L$ and $I_L = K_{ef}(I_s - I_k)$; then

$$I_L = \frac{X}{\frac{1}{K_{ef}} + Y} \tag{1}$$

If K_{ef} is very large, then

$$I_L = \frac{X}{Y} \tag{2}$$

Over the entire range of environmental conditions, regulator amplifiers of this type have been proved to maintain a regulating accuracy of ±0.5% of full scale for variations of I_s from zero to full scale and for 4-to-1 variations in MCT_1 core displacement.

Temperature Measurement

The primary reasons for temperature measurement are to prevent overheating of the reactor core assembly or violent fluctuations in reactivity due to variations in water density changing the moderation. Overheating may occur in several ways:

1. Insufficient or loss of flow due to failure of pumps or closing of isolation valves.
2. Bulk boiling around the fuel elements reducing the heat transfer coefficient and causing unsafe pressures.
3. Excessive power demand from the steam generator causing fuel element internal temperatures to rise above a safe level.

The expansion of fuel elements and other components of the reactor core with overheating mayd istort or buckle the core radically changing the flow and flux distribution patterns. Hot spots then occur which rupture and burn out fuel element assemblies. Bulk boiling can generate large quantities of steam rapidly, causing the pressure to rise quickly to an unsafe value in the manner of a steam boiler explosion.

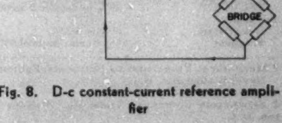

Fig. 8. D-c constant-current reference amplifier

Moderation of the neutron flux changes with the water density and reactor inlet water temperature must be monitored at all times to prevent cold water accidents. These occur if the reactor inlet water temperature is allowed to drop suddenly as might happen if isolation valves were suddenly opened to admit cold water from a loop that had been shut off for some time.

The temperature measurement sets are of three basic types:

1. A single-temperature measurement set (either of wide or narrow range) which gives an output proportional to a single temperature.
2. An average-temperature measurement set (generally narrow range) which gives an output proportional to the average of two temperatures.
3. A differential-temperature measurement set (generally narrow range) which gives an output proportional to the difference between two temperatures.

Single-temperature wide-range indication of reactor inlet temperature T_c is provided for start up. Also during start-up, indication of difference between pressurizer temperature T_p and reactor outlet temperature T_h is used to prevent bulk boiling.

Narrow-range measurement of reactor outlet temperature T_h provides indication, alarm, and scram for dangerously high reactor water temperature. A proportional control current from the T_h measurement set may also be used for automatic rod control.

Average temperature T_{ave} is used for indication and high alarm as well as to provide a proportional control current for rod control when the reactor plant is automatically controlled to a constant average temperature.

Loop differential temperature $T_h - T_c$ is a measure of the reactor thermal power output since flow is a constant value and the power delivered is:

$$\text{Btu/hour} = kF(T_h - T_c) \qquad (3)$$

where

k = a proportionality constant
F = flow, pounds/hour
$(T_h - T_c)$ = differential temperature, degrees

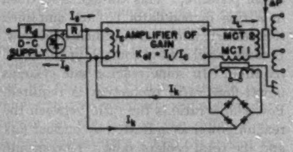

Fig. 9. A-c regulator amplifier

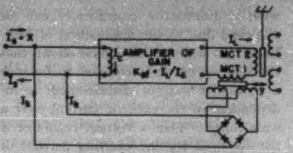

Fig. 10. D-c/a-c quotient amplifier

As previously mentioned, $T_p - T_h$ is used during start-up to indicate the difference between the reactor water temperature and boiling.

$T_c - T_c$ is used to interlock the loop isolation valves to prevent accidental opening of a cold loop and a cold water accident. In case of excessive difference in reactor inlet water temperatures it may also provide scram initiation signals to the reactor safety system.

The basic components of the temperature measurement sets consist of resistance temperature detectors (RTD), a resistance bridge circuit and its d-c constant-current power supply, a readout amplifier to amplify the bridge output and supply a direct current proportional to the measured quantity, indicators for local and remote indication, and bistable amplifiers to operate on-off controls and alarms arranged as shown in Fig. 11.

The RTD is a dual-element type with tungsten resistance elements and was especially developed for radioactive service.[15] Tungsten is used for the element in preference to platinum or nickel since, in a properly compensated and unbalanced bridge circuit with a constant-current input, it provides a linear signal directly proportional to the measured temperature. Its unique mechanical construction provides a high speed of response (0.5 second for 63%) for coolant flows above 5 feet per second as well as complete interchangeability between elements.

Use of a dual resistance element reduces the number of penetrations of the high-pressure piping to a minimum and allows either two temperature measurements at the same point or provides an installed spare.

The RTD in combination with its bridge, constant-current power supply, and readout amplifier provides a 0 to 5-ma d-c signal proportional to temperature from 0 to 700 F and of any span from full range to as low as 50 F. Measurements with a span of much less than 50 F are not practical since the fixed magnitude errors such as amplifier input-stage zero drift and RTD adjustment errors become dominant over the errors that are proportional to span such as indicator error, and increased accuracy does not result from the decreased span. Typical measurement ranges and their associated accuracies are shown in Table II.

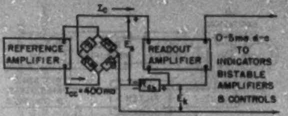

Fig. 11. Block diagram of temperature measurement set

Tests have shown that these accuracies can be maintained over the entire range of environmental conditions including high shock.

By proper choice of bridge balance point, the output current may be made to increase with either increasing or decreasing temperature for fail-safe operation. For a single-temperature measurement the RTD is located at R_1, for average temperature at R_1 and R_3, and for differential temperature at R_1 and R_4 in Fig. 11. The bridge transfer function is

$$E_0 = I_{in}\frac{R_2R_4 - R_1R_3}{R_1 + R_2 + R_3 + R_4} \qquad (4)$$

Pressure Measurement

The two types of pressure measurement sets used are the same except for the pressure transmitters which differ in range and span of measurement.

The wide-range pressure set (P_{wide}) measures loop or reactor pressure over the range of 0 to 2,800 psia (absolute). During a cold reactor start-up it is used by the operator while controlling the pressurizer heaters manually to bring the system up to normal operating pressure. In addition, it may be used to operate high-pressure alarms and electric relief valves if the system pressure rises above a safe value.

The narrow-range pressure set (P_{narrow}) measures pressurizer pressure over a range of approximately 1,800 to 2,500 psia. Its primary purpose is to provide on-off control for the pressurizer heaters to maintain the system within the normal range of operating pressures. In addition, it provides a more accurate indication of

Table II. Measurement Ranges and Associated Accuracies

Measurement	Range, F	Accuracy, F
T_c	0 to 600	±12
T_h	510 to 580	± 3.5
T_{ave}	495 to 545	± 3.5
$T_h - T_c$	0 to 50	± 4.5

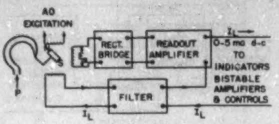

Fig. 12. Block diagram of pressure measurement set

system pressure as well as operating high- and low-pressure alarms, a low-pressure scram initiation, and an electric relief valve.

Frequently a P_{narrow} set is used to provide a safety backup measurement of reactor pressure in case of failure of the primary narrow-range pressure measurement. This narrow-range backup pressure measurement provides local indication of reactor pressure and separate channels for relief valve trip and low-pressure scram.

To provide a greater accuracy of pressure measurement, a new pressure transmitter has been developed for use in a self-balancing measurement system, shown in Fig. 12, with the readout amplifier previously described. In this unit a bourdon tube senses the pressure P and moves the magnet of a magnetic pickoff unit.

The magnetic pickoff unit is a saturable-reactor device having two active core legs with exciting control and signal windings surrounding each leg. When the excitation winding is connected to a source of alternating current, a voltage E_s is induced in the signal winding proportional to the difference between the steady-state magnetic fluxes through the two core legs. Similarly, the signal voltage falls to zero if the two fluxes become equal. Rotation of the permanent magnet from its null position by the bourdon tube produces an unbalance in the core fluxes which results in a proportional increase in the signal voltage. However, the fluxes may be rebalanced and the signal voltage again brought to zero by passing a direct current I_L of proper magnitude through the control winding. Thus the d-c control current necessary to restore the signal voltage to zero is proportional to the pressure applied to the bourdon tube.

Accuracy greater than that obtainable with a differential transformer can be achieved due to the application of feedback. In addition, tests have shown that the control current required to balance a particular magnet displacement is independent of the exciting current over a wide range. Thus a voltage regulator is not required for the exciting current of the magnetic pickoff unit as it is with a differential transformer.

Table III. Measurement Ranges and Associated Accuracies

Measurement	Range, PSIA	Accuracy, PSIA
P_{wide}	0 to 2,800	±76
P_{narrow}	1,900 to 2,500	±35

Adjustment of the output current I_L to the proper value is made automatically by the readout amplifier in a self-balancing circuit similar to that previously described for the temperature sets except that the balancing is done in the magnetic pickoff unit instead of across the resistor R_L, and a filter and rectifier have been added to eliminate interaction between the a-c signal voltage and the amplifier output-stage "hash." The small unbalance signal from the magnetic pickoff is amplified and delivered as a 0 to 5-ma d-c output current to the various indicators, alarms, and controls, and to the control winding of the magnetic pickoff.

The high current gain (K_{ef}) of the readout amplifier maintains the magnetic pickoff very close to balance at all times. Thus, the amplifier output current I_L is determined only by the position of the pickoff magnet and is practically independent of power supply voltage and frequency, amplifier linearity, and load resistance.

Typical pressure measurement set ranges and the associated accuracies for all environment conditions are given in Table III.

Flow Measurement

Flow is not necessarily a critical or extremely important measurement since the main coolant pumps generally can only be operated at half or full speed or shutoff. However, it is desirable to be able to detect and indicate loss of flow from unusual causes such as a loop isolation valve drifting closed or loss of a pump impellor.

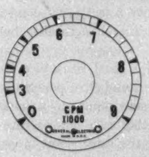

Fig. 13. Flow scale

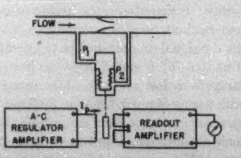

Fig. 14. Block diagram of flow measurement set

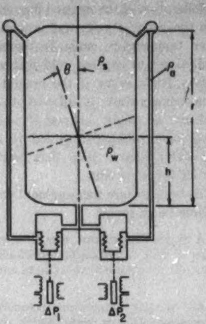

Fig. 15. Pressurizer piping schematic, wide-range external reference legs

In this case flow would be measured by detecting the differential-pressure drop across an elbow or other restriction in the loop piping. The differential pressure generated is:

$$\Delta P = kF^2 \tag{5}$$

where

F = flow, pounds/hour
k = factor which varies with water density and viscosity
ΔP = differential pressure, psi

However, since the accuracy required is not great (approximately ±10% to 20%) and the total flow in all loops is not required, a squared scale shown in Fig. 13 may be used satisfactorily, and density and viscosity compensation are not provided.

A block diagram of a flow measurement set of this type is shown in Fig. 14. In this set the differential pressure across the flow restriction is detected by the movement of a bellows to which is attached the core of an MCT. If the primary current in the MCT is held constant, as the core is displaced it will generate a voltage in the secondary proportional to the differential pressure. This voltage is rectified in a ring demodulator circuit, amplified if necessary, and used to indicate the flow. Usually, no alarms or control functions are required. In some reactor safe systems power-flow ratio protection is required. Power-flow ratio is the ratio between the reactor power as indicated by nuclear flux and the total coolant flow. To compute this ratio, a current proportional to total

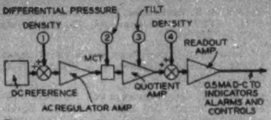

Fig. 16. Block diagram of liquid-level measurement set

flow is needed and this requires that the output current of each flow set be a linear function of flow. Linearization may be achieved where necessary by using compensating springs in the differential-pressure transmitter or by introducing nonlinearities in the readout amplifier.

Liquid-Level Measurement

Liquid level is not a very critical measurement; however, it is an important one and difficult to make accurately. Level is measured in the pressurizer vessel where it is desired to indicate the location of the interface between the water and steam. Indication of this interface is provided locally at the instrument panel, at the main coolant charging station where the operator manually operates valves to discharge or charge the system water as required, and at the main reactor plant control benchboard.

A high-level alarm is provided to indicate insufficient steam space in the pressurizer vessel. This is a hazardous condition since a sudden increase in system temperature would expand the water volume causing an insurge to the pressurizer. If this insurge were not relieved by compression of the steam, the system pressure would rise sharply and perhaps dangerously in the fashion of the familiar "water hammer."

Low-level alarm and pressurizer heater cutoff are also provided. During a severe down-temperature transient an outsurge of water from the pressurizer may uncover the top bank of heaters before the operator can charge the system with enough fresh water to keep the water level within its proper range. Under these conditions, the heater cutoff control turns off the heaters to prevent them from burning out while exposed.

Pressurizer level is usually measured by measuring the differential pressure between the bottom and top of the pressurizer vessel. A schematic arrangement of the pressurizer and its associated piping is shown in Fig. 15. External reference legs are provided with condensate pots which ensure a constant height of water column on the side of the differential-pressure transmitter. The other side is connected directly to the bottom of the pressurizer vessel. Generally, the differential-pressure transmitters are of the bellows type operating the core of an MCT and are similar to those used for flow measurement.

It can be shown for this configuration, assuming that the differential-pressure transmitters and all external piping lie in a plane that passes through the center line of the pressurizer and is perpendicular to the fore-and-aft center line of the boat, that

$$h=\left(\frac{\Delta P_1-\Delta P_2}{2}\right)\times\frac{1}{(\rho_w-\rho_s)}\times\frac{1}{\cos\theta\cos\phi}+r\left(\frac{\rho_a-\rho_s}{\rho_w\rho_s}\right) \quad (6)$$

where

P_1 = differential pressure, external leg 1
P_2 = differential pressure, external leg 2
ρ_a = density of water in external piping
ρ_s = density of steam in pressurizer
ρ_w = density of water in pressurizer
θ = angle of roll
ϕ = angle of pitch
h = height of interface from bottom of pressurizer
r = height of condensate pots from bottom of pressurizer

Thus it is seen that the desired height is a rather complex function involving the density of the water, the steam, and the roll and pitch of the boat.

A block diagram of the liquid-level measurement set which computes the desired height (h) is shown in Fig. 16. As is explained more fully in the following, the computation is carried out by first multiplying $(\Delta P_1-\Delta P_2)/2$ by the factor $1/(\rho_w-\rho_s)$, next dividing the result by the factor $(\cos\theta\cos\phi)$, and finally adding the correction term $r[(\rho_a-\rho_s)/(\rho_w-\rho_s)]$.

The actual differential pressure varies as a function of the pressurizer water and steam density. These densities may be computed from standard steam tables,[18] since the water is boiling, and are plotted as a function of system pressure in Fig. 17. At higher pressure and temperature, the steam density becomes large enough to be important. In fact, it may become as large as 25% of the water density in the operating range of pressures. This means that at some particular level where the height of the steam column is several times that of the water, the effect of the density variations will essentially cancel out and the level measurement will be accurate over wide variations in pressure. A typical pressurizer level density correction curve is shown in Fig. 18.

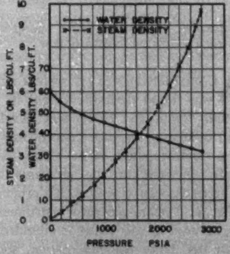

Fig. 17. Saturated water and steam density variation

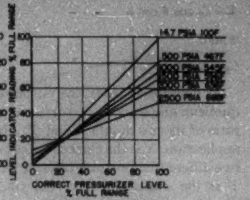

Fig. 18. Density correction curve for typical pressurizer level indicator

To obtain the first density correction, a signal is obtained from the narrow-range pressure measurement set over the normal operating pressure range. During start-up the correction is inserted manually by means of a potentiometer. Referring to Fig. 16 and equation 6, the density correction factor $1/(\rho_w-\rho_s)$ is added as a correction to the d-c reference signal and fed to the input of the a-c regulator amplifier. The output of the a-c regulator amplifier is then a function of density and is used to supply the primary windings of the MCT attached to the differential-pressure transmitters. Since their output is proportional to the product of primary current $1/(\rho_w-\rho_s)$ and core position $(\Delta P_1-\Delta P_2)/2$, the desired multiplication has been performed.

The signal from the differential-pressure transmitters is then fed into the quotient amplifier along with a signal from the tilt compensator. In a land-based plant $\cos\theta=\cos\phi=1$ and may be neglected. For shipboard use, a tilt compensator consisting of an MCT attached to a weight on a spring generates the tilt correction function

Table IV. Measurement Set Ranges and Accuracies

Measurement	Range, Inches of Water	Accuracy, Inches of Water
Wide range	0 to 70	±8
Narrow range	0 to 35	±3

$$Y = C_y \cos\theta \cos\phi \tag{7}$$

where

C_y = constant

As described earlier, the output of the quotient amplifier is proportional to the ratio of its two inputs X and Y. In this application, X is the current output of the two differential-pressure transmitters and Y is the displacement of the tilt compensator given in the foregoing.

After this division the quotient amplifier output is then fed to the readout amplifier input, where it is added to another density correction factor $r[(\rho_a - \rho_s)/(\rho_w - \rho_s)]$ which is generated by the d-c reference and the pressure signal. Thus the desired computations have been performed and the readout amplifier output is 0 to 5 ma d-c proportional to the liquid level h.

Due to the kind and number of manipulations required, liquid-level measurements are less accurate than those of temperature and pressure. Typical liquid-level measurement set ranges and accuracies under all conditions of tilt, pressure, and ambient conditions are shown in Table IV.

Conclusions

Improved main coolant instrumentation for a shipboard pressurized water reactor power plant has been developed using self-balancing amplifiers without moving parts. This instrumentation meets all the functional requirements and provides a high degree of reliability and long life under severe environmental conditions through the use of magnetic amplifier and silicon rectifiers.
